**Lecture - 82**  
**Tutorial on V-n Diagram of Transport Aircraft**

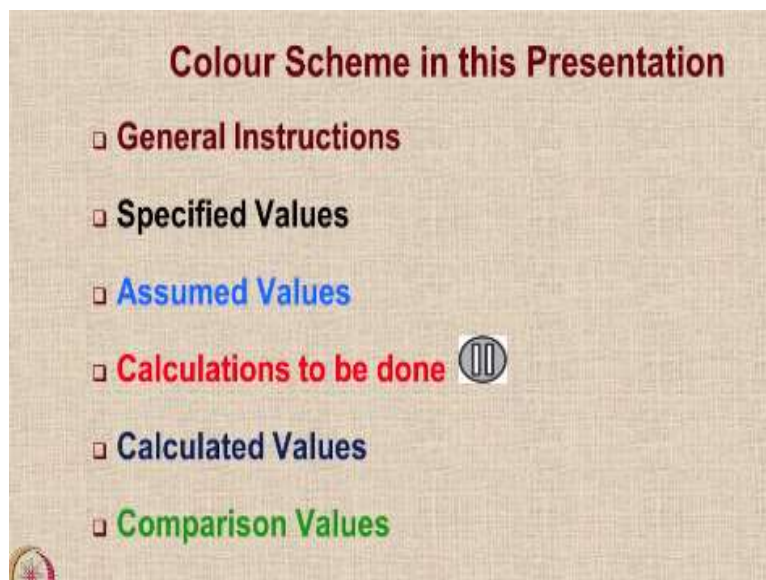

Hello, let us have a look at how the V-n diagram is calculated for a long range transport aircraft.

**(Refer Slide Time: 00:31)**

As is the usual in this course, we have taken Boeing 787 Dreamliner as our reference aircraft.

**(Refer Slide Time: 00:35)**

Let us look at the color scheme in this presentation which is also standard, you must be used to it by now. The general instructions are given in brown color. If there are any values which are specified in any standard document or any online source, which is taken as a reference, they will be shown in the black color. The values which are assumed or which are given in the database are in the light blue color.

Wherever we do you do some calculations, there is a hint that it is in red color and also there is a pause button after that. So I would request if you really want to learn to do these calculations properly. It is best that when you see the pause button you can pause the video, do the required calculations and then proceed further. The values which are calculated are going to be shown in the dark blue color.

And any comparison is going to be in the green color. But in this presentation of course we do not have anything to compare.

**(Refer Slide Time: 01:40)**

Let us first start with a quick recap about what is a V-n diagram. At this point, I suggest if you have not watched the video clips regarding V-n diagram, it is a good idea to first go and watch them and then do the tutorial. But those of you who have already watched the video clips here is a quick recap about a V-n diagram. It is basically a structural operating envelope of the aircraft. In this diagram, we plot the limit load factor versus the airspeed.

But this is applicable only for symmetric maneuvers in the xy plane. We use equivalent airspeed on x axis. The reason for that is very clear, because we want to use the same diagram for various altitudes. Usage of equivalent airspeed allows that to happen. On the y axis, we have the vertical load factor experienced by the aircraft, which is the total vertical force acting divided by the aircraft weight.

This is the largest in magnitude among the three load factors  $N_x$ ,  $N_y$ ,  $N_z$ . So this is actually  $N_z$ , but since we will talk only about one load factor, we are not going to use the subscript z. So when we say load factor N we actually mean the vertical load factor  $N_z$ . And on this particular diagram, the regulatory bodies have suggested that we should superimpose some gust load factors, okay.

**(Refer Slide Time: 03:18)**

Let us look at the steps in the construction of a V-n diagram. So here is the V-n diagram. So first, we normally calculate the value of  $V_s$  which is the stall speed in level flight. It is also called as 1g stall speed. And while calculating this number you use load factor  $N_z = 1$  and V equal to  $V_{stall}$ . And all along this line from O to A the  $C_L$  is actually equal to  $C_{L_{max}}$  at various speeds, okay.

So therefore, this area on the left of this line is the positive stall area. So we cannot have sustained flight in this area because the aircraft is going to stall. So in a way, this gives you an operating limitation that you cannot operate for a long time on the left of the line OA. The next important point is the point D which corresponds to the negative load factor area usually when you have inverted flight.

So here what we do is we calculate the point D as the y axis value will be the most negative permitted value of the load factor, there is minus n max and the corresponding speed V depending on what is the lift coefficient maximum permissible in inverted flight. So just like we got the this point  $V_s$  for 1g level flight this is for you know maximum, this is for the maximum negative.

The next point is point A which is a very important point. It is called as the point of corner speed because the speed corresponding to this point is the corner speed. At this point there are two things which are applicable. The  $C_L$  is equal to  $C_{L_{max}}$  because we are along this line, okay. And also the  $N_z$  is equal to positive  $N_z$  max because we are also on this line.

So this is the intersection of the positive maximum vertical load factor and the smallest speed because it corresponds to the highest value of  $C_L$ . This speed should be as low as possible okay because corresponding to this speed you have the tightest turn and the fastest turn rate. So this is called as the corner speed. This is obtained by the intersection between this line and the maximum permissible load factor line.

The next point of interest is the point corresponding the V-n diagram due to the cruise speed. So cruise speed is either specified or taken as a multiple multiplied fraction of the stall speed 1.25 or 1.5 okay. So here the load factor here is going to be the maximum value and the speed is going to be the maximum permitted cruise speed.

The next important point corresponds to the point where you have the maximum dynamic pressure. So this corresponds to the point which is having the design diving speed and also the  $N_z$  max. So this particular point gives the maximum loading on the aircraft. Therefore, flight on the right hand side of this line is not permitted from the structural safety considerations.

So corresponding to point B there is a point C on the negative load factor. This again corresponds to the most highest negative value of the dynamic pressure. So because it is at design diving speed and the maximum negative value of the load factor. And then

on that we superimpose the gust lines. So first this is a gust line to do a positive gust starting from level flight. So that means  $n = 1$ .

And then as we will see very soon the  $\Delta N_z$  because of gust which is going to be the number above this line is proportional to  $V$ . So it will be a straight line up to  $V_c$ . Similarly, there will be another straight line up to the highest speed at which you are allowed to fly inverted. In this diagram or in this sketch it is shown that this speed is lower than the speed  $V_c$  for the positive flight but it could also be the same.

It depends on the specifications of the aircraft. And then up to design diving speed, we have been asked to also plot the  $\Delta N_z$  both in the positive direction and in the negative direction as shown here. And finally, we just join these lines from cruise to design diving speed both in the top of the graph and the bottom of the graph.

So therefore, if the dark lines shown earlier correspond to the limit maneuver  $V-n$  diagram and if these lines correspond to the limit gust diagram. So if you superimpose these two, this particular curve, the outermost curve is going to be the limit combined envelope.

**(Refer Slide Time: 08:58)**

Data related to Boeing B-787-8			
Aircraft related		Operation related	
• Gross Weight = 476000 lb	= 215912 kg	• Cruise Mach No.	= 0.85
• Wing Area = 3870 ft <sup>2</sup>	= 359.53 m <sup>2</sup>	• Design Cruise Speed = 393 KEAS	= 190 m/s
• Wing Aspect Ratio	= 10.58	• Design Dive Speed = 426 KEAS	= 219.5 m/s
• Sweep of max t/c line	= 30 deg	• Max. +ve Load Factor = 2.54	
• Max. +ve Lift Coefficient	= 1.91	• Max. -ve Load Factor = -1.27	
• Max. -ve Lift Coefficient	= 1.00		

Source: Simos, D., B787-8 Sample Analysis (2005), *PIANO*, [www.piano.aero](http://www.piano.aero)

Now let us start doing the calculations for our aircraft Boeing 787-8. But before we proceed, we need to recall some of the important data and specifications of this aircraft. First, let us look at some aircraft related specifications. This aircraft is designed for a

maximum gross weight of 476,000 pounds, which translates to 215912 kilograms, Wing area is 3870 square feet which translates to 359.53 square meters.

The wing aspect ratio is 10.58. The sweep of the maximum thickness line is 30 degrees. This information will be needed for calculating the value of the lift curve slope which is needed in the estimation of the additional load factor due to gust. Maximum positive lift coefficient is 1.91. And we do not have the value of maximum negative lift coefficient. So we will assume it to be 1.00. Remember this data is not available.

So we have just assumed it. As far as the operation related parameters are concerned, this aircraft has a cruise Mach number of 0.85. Its design cruise speed as specified in the document is 393 knots equivalent airspeed, which can be converted by multiplying by 0.51444 to get meters per second. If you want to do a more accurate conversion, you can multiply the knots with 1852 to convert it into meters, and then divide by 3600 to convert hours into seconds.

Similarly, the design diving speed is given as 426 knots EAS which converts to 219.5 meters per second. The maximum positive load factor that this aircraft is designed to sustain is specified in the sample analysis as 2.54 and we do not have any information regarding what is the maximum negative load factor.

So as specified by the airworthiness agencies, if the designer do not specify the maximum negative load factor, it can be assumed to be at least half of the maximum positive load factor. So please note that the maximum negative lift coefficient of 1 and maximum negative load factor of -1.27 are assumed values in this particular analysis.

**(Refer Slide Time: 11:30)**

Let us look at the FAR-25 regulations for gusts. So these regulations are explained in detail in 14 CFR 25.341 titled Gust and Turbulence Loads. So there is a huge amount of information mentioned in that including things like how to look for changes in the gust velocity etc. We will take a very simple approximation and we will only look at specification of the vertical gust velocity up to the design cruise speed  $V_C$ .

So we need to take the gust speeds to be at least 56 feet per second equivalent airspeed at sea level. They can be reduced to 44 feet per second at the rate of 15,000 feet and at higher altitudes gusts are actually very weak. So therefore, the maximum velocity specified is only 20.86 feet per second equivalent airspeed. So in between, you can always interpolate to the value that you want.

As far as the specification of the gust velocity for the up to the design diving speed, it is considered to be just half of the above values. So this information can be graphically also indicated like this, where you can see that at sea level, we have the highest requirement of gust value gust speed of 56 feet per second which is supposed to be constant up to 15,000 feet. And then from there it is expected to reduce linearly, okay.

Then, if you look at the specifications at 15,000 feet, it is 44 up to 15,000 and then again it is reduced linearly. And if you look at the design diving speed, the value is 20.86 up to 15,000 feet. And then again it is to be linearly reduced. In our case, we are going to look mainly at the situation at sea level. So therefore, we are only going to be concerned with this velocity, 56 feet per second EAS at sea level.

And of course, the value up to design diving speed which will be half of this or 28 feet per second.

(Refer Slide Time: 13:54)

### Calculations at Sea Level

- $V_S @ n = 1$ 

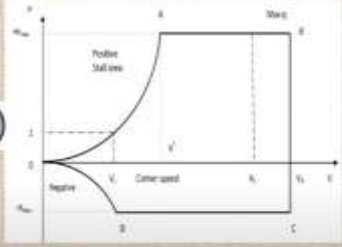

$$V_S = \sqrt{\frac{2Wg}{\rho S C_{L_{max+ve}}}} = \sqrt{\frac{2 \cdot 215912 \cdot 9.807}{1.225 \cdot 359.53 \cdot 1.91}} = ??$$

$$= 70.9 \text{ m/s}$$
- Corner Speed
 
$$V_c = \sqrt{n_{max} V_S} = \sqrt{2.54 \cdot 70.9} = ??$$

$$= 113 \text{ m/s}$$
- $V @ \text{max } -ve n$ 

$$V_{-n} = \sqrt{\frac{2 n_{max -ve} W g}{\rho S C_{L_{max -ve}}}} = \sqrt{\frac{2 \cdot 1.27 \cdot 215912 \cdot 9.807}{1.225 \cdot 359.53 \cdot 1.00}} = ??$$

$$= 97.8 \text{ m/s}$$

The V-n diagram shows the relationship between load factor (n) on the vertical axis and velocity (V) on the horizontal axis. The upper curve represents positive load factors, starting from a stall speed  $V_S$  at  $n=1$  and rising to a maximum load factor  $n_{max}$ . The lower curve represents negative load factors, starting from a stall speed  $V_{-n}$  at  $n=-1$  and rising to a maximum negative load factor  $n_{max -ve}$ . The corner speed  $V_c$  is the velocity at which the aircraft is operating at  $n_{max}$ . The diagram is divided into regions A, B, C, and D.

Let us look at the calculations at sea level. So this is our V-n diagram for a reference. First let us find out the value of stall speed at  $n = 1$ . That means the 1g level stall speed.

And we have to use  $C_{L_{max}}$  positive which is 1.91. So at sea level conditions if you replace these, if you replace these symbols with the appropriate values, you should be able to get the estimate of the stall speed. At this stage, I would request you to pause the video and do this calculation. The value turns out to be 70 meters per second.

So the 1g level stall speed for this aircraft is 70 meters per second under sea level ISA conditions. Next we look at the corner speed. Remember for the corner speed, we both have  $C_L$  equal to  $C_{L_{max}}$  positive and load factor  $n$  will be equal to this  $n_{max}$  which is 2.54. So you can see that the value for corner speed will come from the same equation except  $W$  will be replaced by  $n_z \text{ max times } W$ .

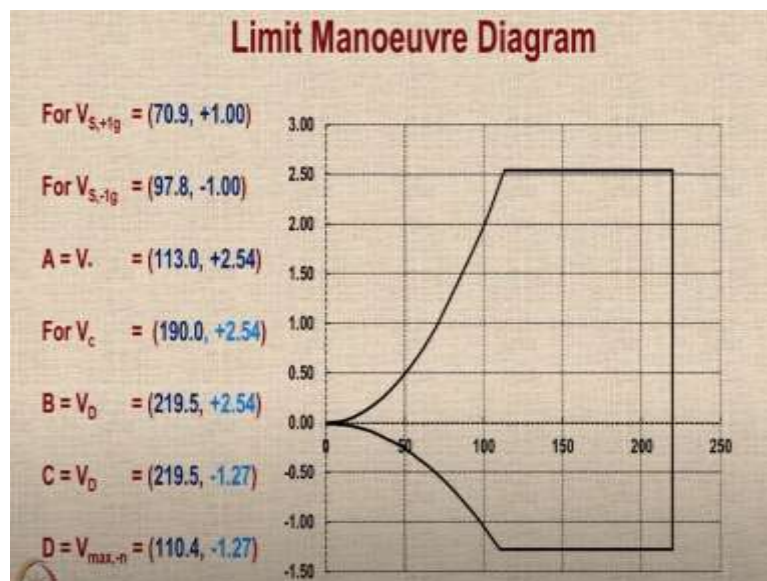

So therefore, what we can do is we can just assume it to be  $V^*$  will be assumed to be or calculated. Please pause the video. Do this calculation. The value turns out to be 113 meters per second. Next, we look at what is the value of velocity when  $n$  is the maximum negative value.

That means we want to get the value of  $V$  corresponding to this particular point, okay. So at that point again the formula is same only we replace  $n$  with  $n$  max negative and we replace  $C_L$  with  $C_L$  max negative, okay. Be careful about the signs because we are going to have a square root. So because I know that in the numerator we have  $-1.27$  the load factor and the denominator we have  $-1$ .

Therefore, I have just avoided putting the minus sign and I am getting the value directly. At this stage please pause the video and have a look at the calculation. So  $V$  at  $-n$  is going to be  $97.8$  meters per second. These three values please remember because we will need them in the future when we plot our  $V$ - $n$  diagram.

**(Refer Slide Time: 16:58)**

So this is our limit maneuver diagram or the limits imposed because of the maneuvers in the study at  $z$  plane okay. So the first number that we have already calculated is this particular point which corresponds to the stalling speed in  $1g$  level flight. So  $n$  is equal to  $1$  and  $V$  as we just now calculate it is  $70.9$  meters per second. The next point is the point that corresponds to  $-1$  the value of stalling speed at  $-1g$ .

So what is the  $-1g$  level flight stalling speed in inverted flight. So this one will be also along the same line and the only thing is  $n$  will be equal to  $-1$ . So for that there is a corresponding value of  $97.8$  meters per second. The next point is the corner speed, which we have just now calculated corresponding to maximum  $n_z$   $2.54$  and also along this line. So the intersection of these two lines that is  $V^*$  the corner speed.

The value of the coefficients of this particular point are going to be for the x axis it will be 113.0, that is the corner speed value and for the y axis it is going to be 2.54. Next point is the design cruising speed point. So this particular the contents of this point if you see here, they will correspond to cruising speed which is 190 and the value of  $n_z$  here is maximum. So for  $V_c$  we have this particular point.

The next point is point B which corresponds to the maximum design diving speed and also the maximum load factor. So that would be 219.5 and +2.54. Corresponding to B there will be a similar point C which will have the same design diving speed value 219.5 but  $n_z$  is going to be now the maximum negative which is -1.27.

And finally, we have the point D where we have the value of velocity at which the load factor has the maximum negative value of -1.27. So you are on this particular line and on this line  $C_L$  will be maximum  $C_L$  permitted for inverted flight or in the negative condition maximum negative  $C_L$  and  $n_z$  will be the maximum negative permitted load factor.

So this point is analogous to the corner speed, but it is in inverted flight, okay. So this is the limit maneuver diagram which we have already plotted for this particular aircraft.

**(Refer Slide Time: 19:50)**

**Additional Gust Load Factor ( $\Delta n_g$ )**

- $\Delta n_g = \frac{ak_g V_g V_c \rho S_w}{2W}$ , where  $k_g = \frac{0.88\mu_g}{\mu_g + 1}$  and  $\mu_g = \frac{2W}{aS_w \bar{c}}$
- $a = \frac{dC_L}{d\alpha} = \frac{2\pi A}{2 + \sqrt{4 + A^2 \beta^2 (1 + \frac{\tau \tan^2 \Delta_m}{\beta^2})}}$ , where  $\beta = \sqrt{1 - M_{cr}^2}$
- Note:-  
 $V_g$  = Vertical Gust Speed,  $V_c$  = Cruise Speed,  $\rho$  = density of air  
 $W$  = Aircraft Weight,  $S_w$  = Wing Reference Area  
 $A$  = Wing Aspect Ratio,  $\Delta_m$  = Sweep of Wing t/c<sub>max</sub> line  
 $\bar{c}$  = Mean Wing Chord

Let us now look at how to estimate the additional gust load factor and how additional limits get imposed in the V-n diagram due to these additional gust loads. For that recall

from the previous video on V-n diagram, we have already shown there that the additional load factor due to a gust

$$\Delta n_g = \frac{a k_g V_g V_c \rho S_w}{2W}$$

Here  $k_g$  is the gust alleviation factor, So we notice that larger the wing loading W/S, smaller the lift curve slope and smaller the chord larger is the value of  $\mu_g$  and then that adds that adds in the calculations here, okay.

So now the value of  $a$  that is needed here for the calculation of lift curve slope and also here for the calculation of  $\mu_g$  is the  $\frac{dC_l}{d\alpha}$  of the aircraft, which can be shown to be

$$a = \frac{dC_l}{d\alpha} = \frac{2\pi A}{2 + \sqrt{4 + A^2 \beta^2 \left(1 + \frac{\tan^2 \Lambda_m}{\beta^2}\right)}}$$

So where this  $\Lambda_m$   $\beta$   $A$  are aircraft related parameters.  $\beta$  is basically

$$\beta = \sqrt{1 - M_{cr}^2}$$

So in this case  $V_g$  here is the specified vertical gust speed which we just now saw.  $V_c$  is the cruise speed or the diving speed depending on which condition we calculate.  $\rho$  is the density of air which is used in the calculations here. Then  $W$  is the aircraft weight that is this  $W$  and  $S$  is the wing area. Many people use  $W/S$  directly in this particular calculation. So in that case  $S$  comes below and this comes 2 into  $W$  by  $S$  okay.

the value  $A$  here is the wing aspect ratio as I mentioned to you  $\Lambda_m$  is the sweep of the maximum thickness chord line. And  $\bar{c}$  is the mean wing chord. So armed with this information, we will now first calculate the lift curve slope for this aircraft. Then using that we will calculate the value of  $\mu_g$ . Once we know  $\mu_g$  we will calculate the value of  $k_g$ .

And once we know  $k_g$  we can put  $k_g$  here in the expression and get  $\Delta n_g$ . which means you already are flying at a load factor of 1. And either on that there is a vertical downward gust or a vertical upward gust. Depending on that we use either plus or minus.

**(Refer Slide Time: 23:14)**

### Estimation of Lift Curve Slope

- $a = \frac{d_{CL}}{d\alpha} = \frac{2\pi A}{2 + \sqrt{4 + A^2 \beta^2 (1 + \frac{\tan^2 \Delta_m}{\beta^2})}}$ , where  $\beta = \sqrt{1 - M_{cr}^2}$
- $\beta = \sqrt{1 - M_{cr}^2} = \beta = \sqrt{1 - 0.85^2} = ??$
- $\beta = 0.5268$
- $a = \frac{2\pi A}{2 + \sqrt{4 + A^2 \beta^2 (1 + \frac{\tan^2 \Delta_m}{\beta^2})}} = \frac{2\pi 10.58}{2 + \sqrt{4 + 10.58^2 \cdot 0.5268^2 (1 + \frac{\tan^2(30^\circ)}{0.5268^2})}} = ??$
- $a = 6.327$

Let us estimate the lift curve slope of this aircraft. So the formula for that I have just reproduced from the previous slide. Now  $\beta = \sqrt{1 - M_{cr}^2}$ . So please calculate this number. It turns out to be 0.5268. So now that we know beta we can actually calculate the lift curve slope by putting all the numbers in this big formula.

So I would like you to pause the video and do this calculation and then compare with the value that I got. The value that I got is  $a = 6.327$ . This is actually per degree because 30 is 30 degrees here, okay. Okay.

**(Refer Slide Time: 24:13)**

### Estimation of Gust Load Factors

<p><b>@ Design Cruising Speed <math>V_c</math></b></p> <ul style="list-style-type: none"> <li>• <math>\mu_g = \frac{2W}{a S_w \bar{c}} = \frac{2 \cdot 215912}{6.327 \cdot 359.53 \cdot 6.465} = ??</math></li> <li>• = 23.93</li> <li>• <math>V_g = 56.00/3.28 = 17.07 \text{ m/s}</math></li> <li>• <math>k_g = \frac{0.88 \mu_g}{\mu_g + 1} = \frac{0.88 \cdot 23.93}{23.93 + 1} = ??</math></li> <li>• = 0.7204</li> <li>• <math>n_g = 1 \pm \Delta n_g = 1 \pm \frac{a k_g V_g V_c \rho S_w}{2W}</math></li> <li>• <math>n_g = 1 \pm \frac{6.327 \cdot 0.7204 \cdot 1.225 \cdot 359.53 \cdot 17.07 V_c}{2 \cdot 215912 \cdot 9.807} = ??</math></li> <li>• <math>n_g = 1 \pm 0.008091 V_c</math></li> </ul>	<p><b>@ Design Diving Speed <math>V_D</math></b></p> <ul style="list-style-type: none"> <li>• <math>n_g = 1 \pm \Delta n_g = 1 \pm \frac{a k_g V_g V_D \rho S_w}{2W}</math></li> <li>• <math>V_g = \frac{1}{2} \cdot 56.00/3.28 = 8.54 \text{ m/s}</math></li> <li>• <math>\Delta n_g = \frac{6.327 \cdot 0.7204 \cdot 1.225 \cdot 359.53 \cdot 8.54 V_D}{2 \cdot 215912 \cdot 9.807} = ??</math></li> <li>• <math>\Delta n_g = \pm 0.004053 V_D</math></li> <li>• <math>n_g = 1 \pm 0.004053 V_D</math></li> </ul>
--	---

Now armed with the information let us now estimate the gust load factor. First we examine the gust load factors at the design cruising speed. So you know that  $\mu_g$  is equal

to  $\frac{2W}{\rho S_w \bar{c}}$ ,  $a$  has just been calculated as 6.327.  $S_w$  is given 359.53.  $\bar{c}$  is given 6.465.  $W$  is given 21592 kilograms. So just multiply by 2. So let us pause here and calculate the value. The value is 23.93.

Moving ahead, the specified value for the gust speed at sea level was 56 feet per second. You will divide by 3.28 to convert it to meters per second and  $k_g$  which will be used in the calculation for  $\Delta n_g$ . Once you know the value of  $\mu$ , you can get the gust elevation factor  $k_g$ . Please calculate this value.

This number comes out to be 0.7204. So what it means is that a vertical gust acting on this aircraft, the sharp vertical gust will actually be reduced by a factor of around 28% to 0.7204. So the additional load factor created because of a vertical gust is going to be reduced by a factor of around 28% because of the value of  $k_g$  which is an aircraft specific parameter.

It depends upon the wing loading, it depends upon the lift curve slope and the span chord of the aircraft, okay. And what we have done here is we have just reproduced a 6.3272,  $k_g$  as 0.7204,  $V_g$  as 17.07,  $V_c$  remains as it is,  $\rho$  is 1.225 and  $S_w$  is 359.53.

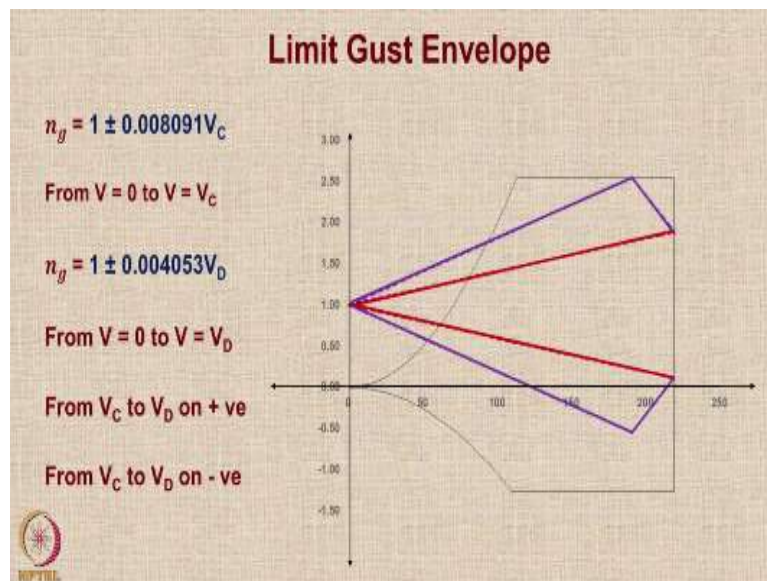

And on the bottom we have replaced  $W$  by  $W$  into  $g$ . So just to take care of the units, okay. So please calculate the value of this whole expression. So it will be 1 plus a constant times  $V_c$ . That number turns out to be 0.008091. So additional gust would be this number times the cruise speed and that will add or subtract from 1 because it will act in the level flight either as a vertical upward gust in which case you will add it or a vertical downward goes in which you will subtract it.

Similarly, we have to apply the conditions for the design diving speed  $V_d$ . Remember, formula remains the same except that instead of  $V_c$  now we will have  $V_d$  in the numerator. And also we have to be careful that the value of the gusts speed  $V_g$  is also going to change. Because you know that  $V_g$  is specified as half of the value at the cruising speed. So the value of  $V_g$  will be half.

It will be 8.54 meters per second as compared to 17.07 meters per second. So substituting the values in the formula  $\Delta n_g$  equals 6.327 which is a. These are the other parameters like area okay weight  $n_g$  etc. I would like you to pause and calculate the value of  $\Delta n_g$ . The value comes to be 0.004053 times  $V_d$  okay. So therefore,  $n_g$  the gust load factor due to vertical and downward gust acting at the design diving speed would vary as the speed.

So from 0 to  $V_d$  with this particular formula  $1 \pm 0.004053$ . So notice that this  $n_g$  versus  $V$  will be a straight line and it will start from  $V_c = 0$  it will become 1 and when  $V_c$  equal to whatever value is there for the design cruise speed it will add a number to that. So it will be a straight line with origin from the point 0, 1 okay. Similarly here.

**(Refer Slide Time: 28:57)**

So let us look at the limit gust envelope. So the first equation is  $n_g$  equal to  $1 \pm 0.008091V_c$ . This is for the vertical gusts acting up to the cruising velocity when the gust speed is 56 feet per second. So from  $V$  equal to zero to  $V$  equal to  $V_c$ , we will just get two lines like this, where this point will correspond to you know it will correspond to 0, 1 level flight.

And as  $V$  changes as per this expression, the  $n_z$  value will be  $1 + 0.008091V_c$ . And this line will correspond to the value when you have  $V_c$  when you have from 0 to  $V_c$  when you have  $1 - 0.008091$  times  $V_c$ . Similarly, if we look at the line for the additional load

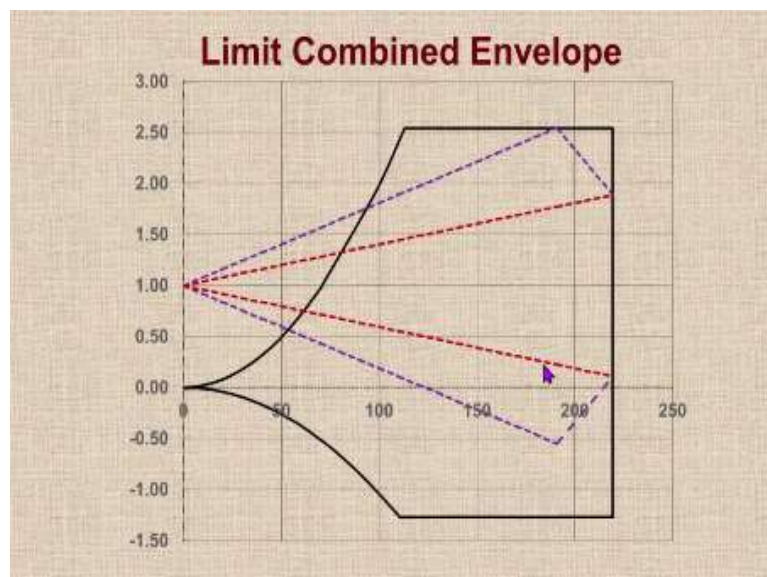

factor up to the design diving speed, so we notice that once again we get two lines, which start from the same point 0, 1.

One of them increases, the other of them decreases. This increases because this is equal to 1 plus a number, which is never going to become less. It is only going to only increase and this is going to be 1 minus a number okay. So that will depend upon the values. And you can see that even when you are at design diving speed, you still have some vertical load factor.

And then finally, what we do is, we just join these from straight lines from  $V_c$  to  $V_d$  on positive and from  $V_c$  to  $V_d$  on negative. So this is the limit gust envelope. That means, if you are in a if you are flying an aircraft, and if there is a gust acting on the aircraft, in level flight the aircraft can go into any of these areas. So the aircraft has to be strong enough to withstand the loads that come when the operating point is within this particular area.

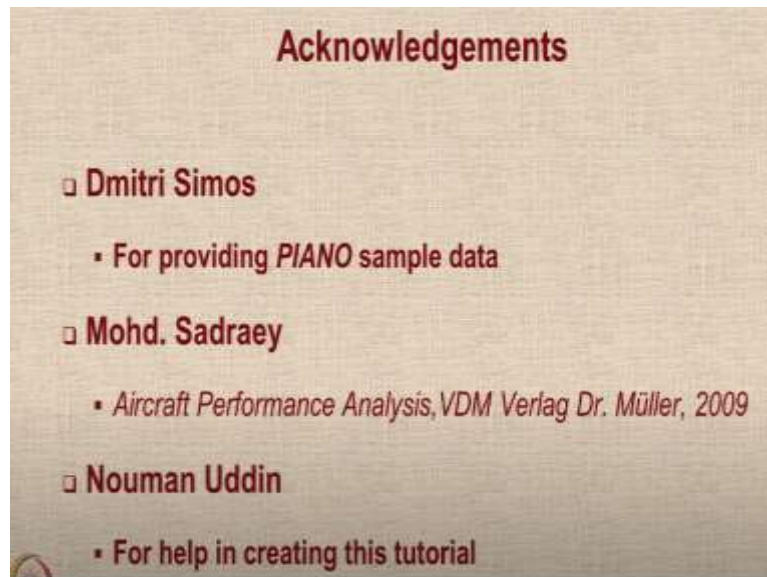

So on this I have just superimposed the previous V-n diagram. So we see that there is not any problem because of gust, no additional material comes out. I mean, the gust envelope is almost completely inside the general maneuver envelope. So in this case, it turns out that the gusts are not imposing any additional limits. But that is not true always. That is not always true.

**(Refer Slide Time: 31:42)**

So here is our limit combined envelope. Here is our limit combined envelope in which the dotted lines represents the additional load factor imposed due to the vertical gusts which are known to be or taken to be 56 feet per second for up to design cruising speed and half of that up to design diving speed, both in the positive axis and in the negative axis.

**(Refer Slide Time: 32:15)**

So thank you so much for your attention. I would like to acknowledge the contribution of the Dmitri Simos for providing the PIANO sample data which we have used in this calculation, Professor Mohd. Sadraey for his excellent textbook on Aircraft Performance Analysis, in which this particular V-n diagram calculation procedure is very nicely and lucidly explained.

And I have taken it from there and also some of the sketches that you have seen in this presentation. And last but not the least, I like to thank Nouman Uddin for help in creating this tutorial and plotting the V-n diagram. Thank you.
