**Lecture No. # 06**

**Lipids**

In my earlier classes, I have already mentioned you about some of the macromolecules molecules present in the cell. Those macromolecules are either protein or carbohydrates or nucleic acids. Most of these macromolecules were soluble in nature. Today, I will be taking about a new molecule which are there in the cell but, it has got little different behavioral or different properties. Those types of macromolecules are called lipid.

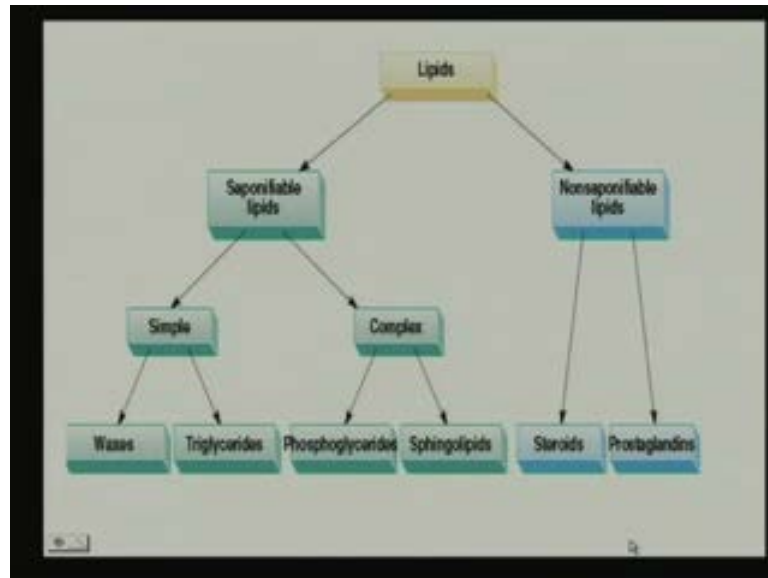

(Refer Slide Time: 01:02)

Now, if you see the lipids, then lipids are the nonpolar molecules that include fats, cholesterol, fatty acids, lipid-soluble vitamins, waxes, soaps and so on. Lipids consist of a broad group of compounds that are generally soluble in organic solvents and only sparingly soluble in water. Now, when we are taking about this lipid, this lipid molecule is present in every cell irrespective of microbial plants and animals. So, if you want to

extract this lipid molecule, being nonpolar in nature, we have to use some solvent like chloroform benzene and so on, to extract this lipid molecule from the cell.

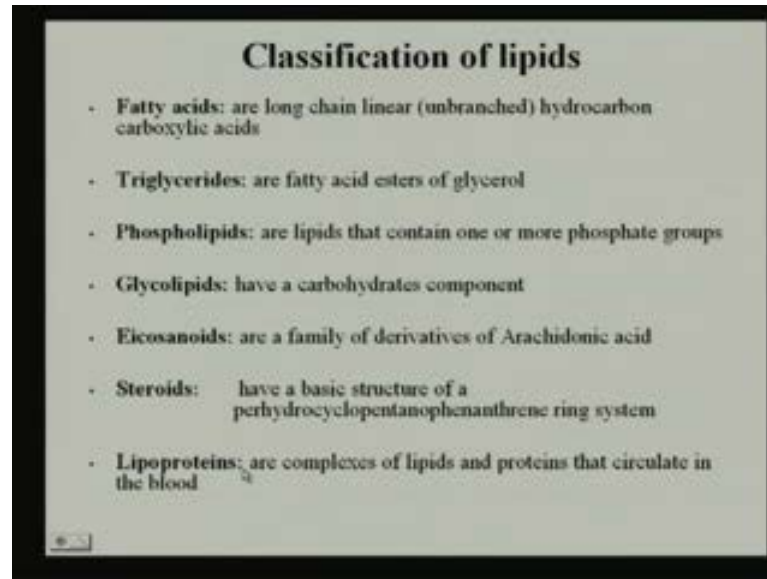

(Refer Slide Time: 02:03)

Now obviously, when I am taking about this particular macromolecule, so if we classify this lipid, entire lipid molecules, then we will find that the entire lipid molecule can be divided into two broad pairs like saponifiable lipid and nonsaponifiable lipid. That means, one type of lipid has some characteristics of soap formation and this type of lipids are further divided into simple lipid and complex lipid.

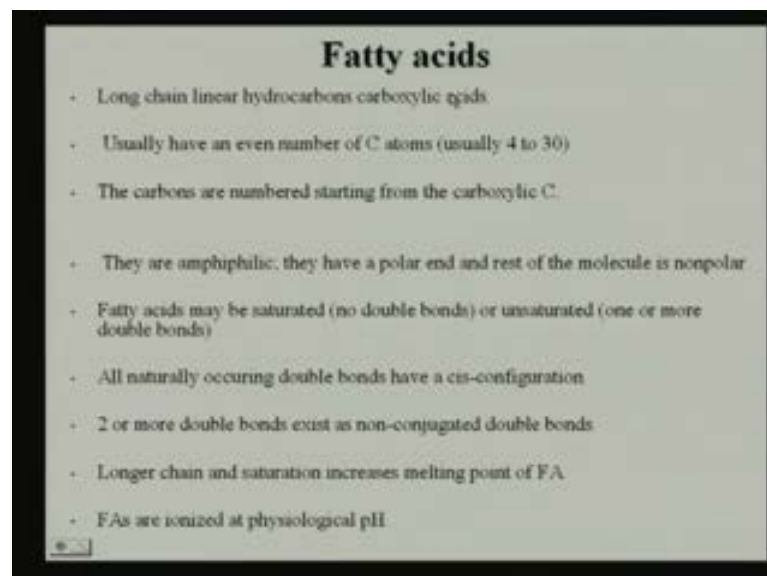

So, these particular classifications have been done based on the structural or this structural behavior of this lipid contain of the lipid molecule. Now, another group is the nonsaponifiable lipid steroid and prostaglandins are some of the example of that. Now, as I have mentioned that the classification is done based on the backbone structure of these lipid moieties.

(Refer Slide Time: 03:16)

So, obviously the structure of these lipid molecules is coming to the picture. Now, when we are doing this classification, fatty acid is one of such long chain linear unbranched hydrocarbon, which is present in the lipid moieties. It has got a carboxylic acid group present attached to its core moieties. Triglycerides, phospholipids, glycolipids, eicosanoids lipids, steroids, lipoproteins are the different types of lipids which are there present in the lipid family.

(Refer Slide Time: 04:08)

Now, let us come one by one. When we are talking about this fatty acid, it is the long chain linear hydrocarbon having that carboxylic acid end. Now, that means, it has got a carboxylic acid end.

(Refer Slide Time: 04:28)

Now, if we are talking about this particular acid, then this carboxylic group which is there and if we considered about this chain then, we can find that this fatty acid has got one carboxylic end group, which is polar in nature and nonpolar chain like structure. That is, the tail part, one is the head and another is the tail. This hydrocarbon chain is the long chain, which is attached to this carboxylic end of this fatty acid. The chain length can be varied from four to thirty. The carbon, a number starting from this carboxylic end, that means, this is the carbon atom number 1 when it is 2 3 4 5 6 7 8 9. That way the numbering is done.

Now, it is amphipathic in nature. That means, it has got one polar end and one nonpolar end. Fatty acids may be saturated or unsaturated. That means, when we can tell that fatty acid is saturated, that means entire fatty acid can be divided into two parts. One is called the saturated fatty acid and another is the unsaturated fatty acid. Now, when this is saturated fatty acid? When there is no double bond present in this fatty acid. There is only the linear chain along with a carboxyl end. This chain length may get very different depending upon the nature of that fatty acid. But, when the double bond is present in between the nonpolar tail group, then we are calling, we call that type of fatty acid as the

unsaturated fatty acid. All naturally occurring double bonds had a cis-configuration. So, most of this double bonds are, either it can be found either in the cis form or in the trans form. So, in most of the cases, this fatty acids are found in the cis form. I will be coming to this, the positional, this, what is cis and trans gradually. Now, two or more double bonds exist as non-conjugated double bonds and longer fatty acid and saturation increases the melting point of the fatty acid. Fatty acid gets ionized at physiological pH. That means, at pH around 7.4.

(Refer Slide Time: 07:42)

Now, as I have already discussed the structure, you see, here is a long chain which is the tail group. Nonpolar hydrophobic tail, which is water insoluble and here, the polar end which is hydrophilic in nature and this is the head group. So, we will present this COOH as the polar and the tail, which is attached as the nonpolar.

(Refer Slide Time: 08:19)

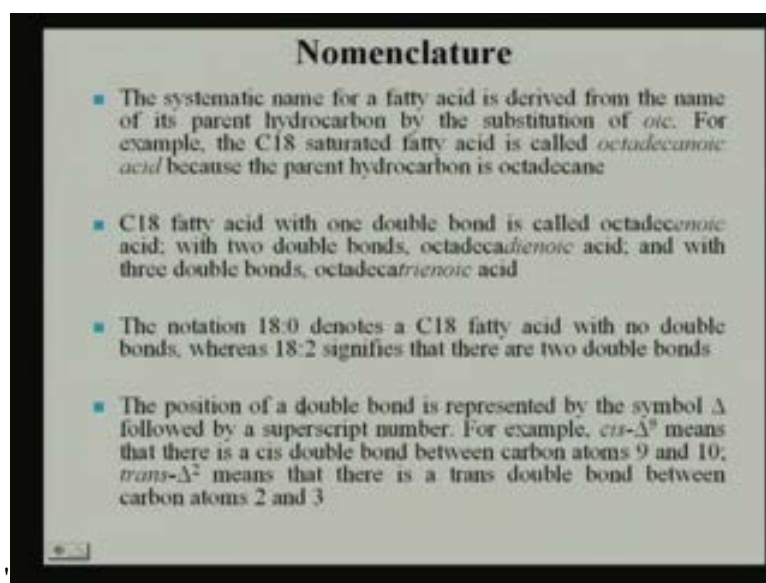

This fatty acid is once again classified into saturated and unsaturated. Sometimes, it is the branched fatty acid, substituted fatty acid and cyclic fatty acid. That means, besides this saturated and unsaturated, we can also get this fatty acid in a much more complex form. That means, sometimes we are getting it in the branched condition, substituted condition and sometimes we are getting in a cyclic form. When we are taking about the unsaturated fatty acid, it may be monoenoic acid, dienoic acid, trienoic acid, tetraenoic acid and so on.

(Refer Slide Time: 09:08)

Compound type and number of carbons	Name	Formula	Melting point (°C)	Common sources
Saturated				
14	Myristic acid	$\text{CH}_3(\text{CH}_2)_{12}\text{-COOH}$	54	Butterfat, coconut oil, nutmeg oil
16	Palmitic acid	$\text{CH}_3(\text{CH}_2)_{14}\text{-COOH}$	63	Lard, beef fat, butterfat, cottonseed oil
18	Stearic acid	$\text{CH}_3(\text{CH}_2)_{16}\text{-COOH}$	70	Lard, beef fat, butterfat, cottonseed oil
20	Arachidic acid	$\text{CH}_3(\text{CH}_2)_{18}\text{-COOH}$	76	Peanut oil

Now, coming to the saturated fatty acid. As I have mentioned already, that saturated fatty acid has no double bond within it. If we are considering the total number of carbon present is 14, then myristic acid is one of the example. Now here, you see, total C carbon, the number of carbon atom present in this fatty acid is 14. We can get this type of fatty acid in butter fat, coconut oil and so on. When we are considering the 16 carbon molecule, then it is the palmitic acid. Here also, no double bonds are there. So here, 18 carbon is the stearic acid and so on. This way, the number is getting increased and the property and the characteristics are also getting changed. Now, this palmitic acid is found in lard, beef fat, coconut seed oil and so on. So, these are the common examples of saturated fatty acid.

(Refer Slide Time: 10:23)

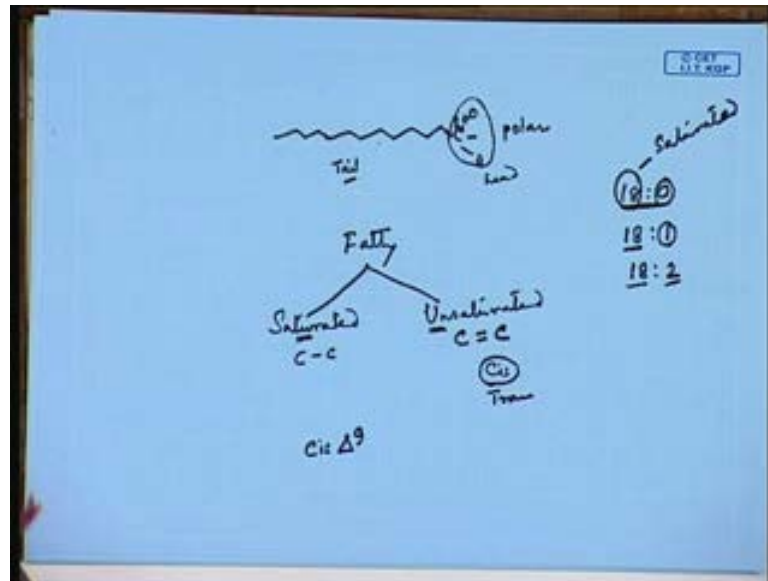

**Nomenclature**

- The systematic name for a fatty acid is derived from the name of its parent hydrocarbon by the substitution of *oic*. For example, the C18 saturated fatty acid is called *octadecanoic acid* because the parent hydrocarbon is octadecane
- C18 fatty acid with one double bond is called *octadecenoic acid*; with two double bonds, *octadecadienoic acid*; and with three double bonds, *octadecatrienoic acid*
- The notation 18:0 denotes a C18 fatty acid with no double bonds, whereas 18:2 signifies that there are two double bonds
- The position of a double bond is represented by the symbol  $\Delta$  followed by a superscript number. For example, *cis*- $\Delta^9$  means that there is a *cis* double bond between carbon atoms 9 and 10; *trans*- $\Delta^2$  means that there is a *trans* double bond between carbon atoms 2 and 3

Now, coming to the nomenclature. The systematic name of the fatty acid is derived from the name of the parent hydrocarbon by the substitution of *oic*. For example, the C18 saturated fatty acid is called C18. That means, 18 carbon containing chain, that is octadecanoic acid. So, because the parent hydrocarbon is the octadecane, C18 fatty acid if it is having double bond then it is called octadecanoic acid. If two double bonds are there, then octadecadienoic acid and with three double bonds, then octadecatrienoic acid. Depending upon, as I have mentioned that, monoenoic, dienoic, trienoic, tetraenoic in that way, the naming has been done.

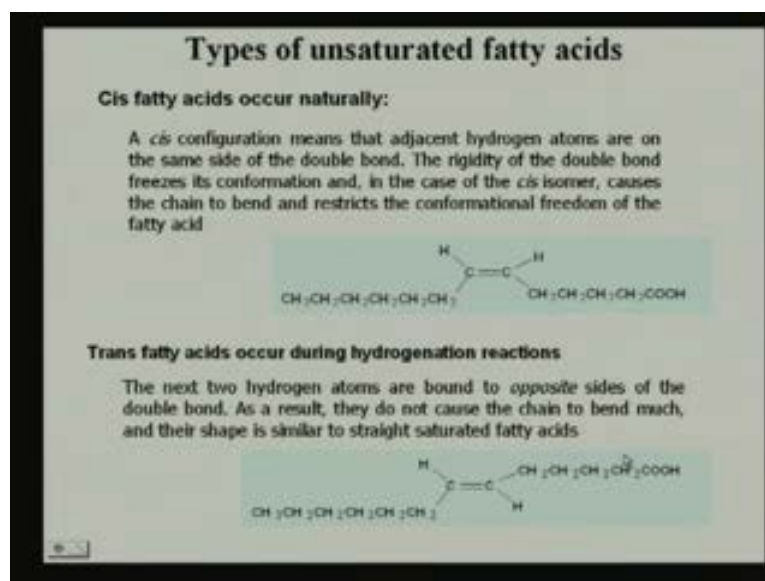

(Refer Slide Time: 11:43)

Now, sometimes we are getting some symbol like 18 is to 0. Sometimes, we are getting 18 is to 1. Sometimes, it is 18 is to 2. What is it mean? It means that, fatty acid is having 18 carbon atom and it has no double bond. That means, it is a saturated fatty acid. When we are getting 18 is to 1, that indicates that, 18 carbon atom containing fatty acid, the chain and one double bond is present in this. 18 is to 2, that means, 18 carbon fatty acid and two numbers of double bonds are present in this particular molecule. So, how it will be? This is the meaning of this particular 18 is to 1, 18 is to 2, 18 is to 0 and so on. The position of double bond is represented by the symbol delta followed by a superscript number. That means, if suppose the bond is cis type of bond and if it is written delta to the power 9, what does it mean. That means that, this fatty acid is arranged in a cis-configuration and this double bond is present in carbon atom 9 and 10. So and if it is suppose, trans delta 2, it means that there is a trans double bond between carbon atom 2 and 3. In this way, the numbering is done.

(Refer Slide Time: 13:33)

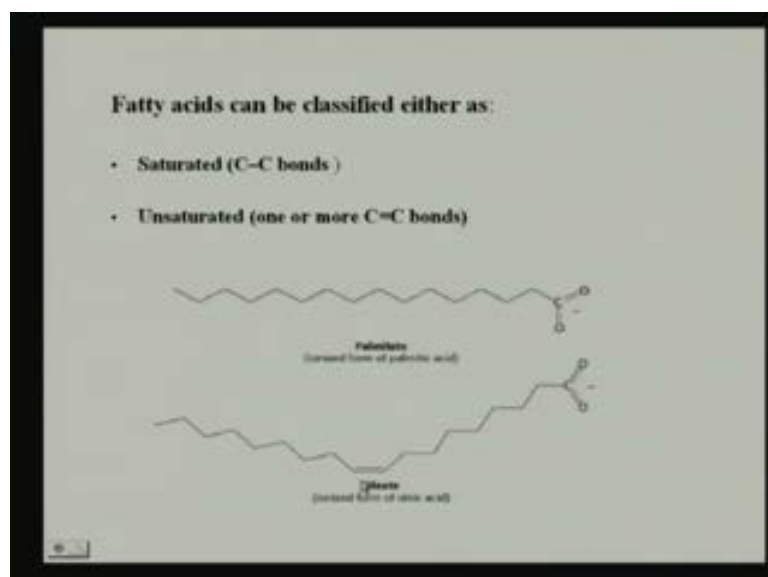

Now, if suppose, we are taking about the *cis* and *trans* configuration, then we can find that a *cis*-configuration means that the adjacent hydrocarbon atom is on the same side. See here. It is on the same side of the double bond. The rigidity of the double bond freezes the conformation and in the case of *Cis* isomer, causes a chain to bend and restricts the conformational freedom of the fatty acid. That means, in this type of configuration, we can find a kink in this fatty acid chain where this double bond is present. In case of this *trans* fatty acid, the next two hydrogen atoms are bonded in the opposite side of the double bond. As a result, they do not cause the change to bend much and their shape is similar to straight saturated fatty acid. So, this is the *trans* form of this fatty acid; transformed arrangement. Here, as their positions are like this, they do not get, we do not get a much kink or bend in this double bond side.

(Refer Slide Time: 15:12)

Compound type and number of carbons	Name	Formula	Melting point (°C)	Common sources
<b>Monounsaturated</b>				
16	Palmitoleic acid	$\text{CH}_3(\text{CH}_2)_5\text{CH}=\text{CH}(\text{CH}_2)_7\text{COOH}$	-1	Cod liver oil, butterfat
18	Oleic acid	$\text{CH}_3(\text{CH}_2)_7\text{CH}=\text{CH}(\text{CH}_2)_7\text{COOH}$	13	Lard, beef fat, olive oil, peanut oil
<b>Polyunsaturated</b>				
18	Linoleic acid	$\text{CH}_3(\text{CH}_2)_4(\text{CH}=\text{CHCH}_2)_2(\text{CH}_2)_6\text{COOH}$	-5	Cottonseed oil, soybean oil, canola, linseed oil
18	Linolenic acid	$\text{CH}_3(\text{CH}_2)(\text{CH}=\text{CHCH}_2)_3(\text{CH}_2)_4\text{COOH}$	-11	Linseed oil
20	Arachidonic acid	$\text{CH}_3(\text{CH}_2)_4(\text{CH}=\text{CHCH}_2)_4(\text{CH}_2)_2\text{COOH}$	-30	Linseed oil, corn oil
20	Eicosapentaenoic acid	$\text{CH}_3(\text{CH}_2)(\text{CH}=\text{CHCH}_2)_5(\text{CH}_2)_2\text{COOH}$		Canola, linseed oil, animal tissues
22	Docosahexaenoic acid	$\text{CH}_3(\text{CH}_2)(\text{CH}=\text{CHCH}_2)_6\text{CH}_2\text{COOH}$		Fish oil, seafoods

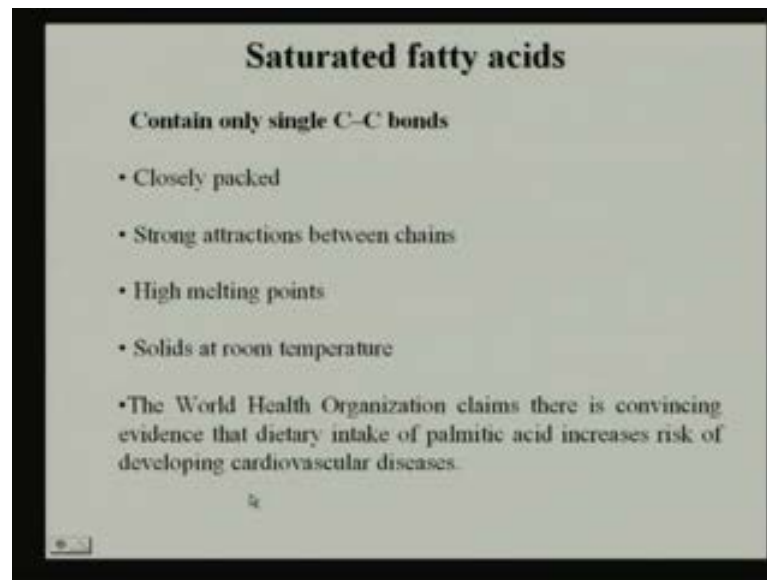

Now, if we see some of this example of the monounsaturated fatty acid and polyunsaturated fatty acid, then we can find that palmitic acid, oleic acid, linoleic acid, linolenic acid and so on, this is depending upon the carbon chain. Number of fatty acids, the naming has been done. So here, in case of palmitoleic acid, here you see, here only one double bond is there. When we are considering oleic acid, then here you can find that here also, single bond is there. In case of polyunsaturated fatty acid and linoleic acid, we are getting two double bond. Linolenic acid, we are getting three double bond and so on.

(Refer Slide Time: 16:18)

So, this way the chain is getting increased. So here, you see this is the saturated fatty acid and this is the unsaturated fatty acid. See, 1 2 3 4 5 6 7 8 9 and 10 carbon atom. So, when I am talking about cis delta 9, that means in between 9th and 10th carbon atom, the double bond is present and it is the oleic acid.

(Refer Slide Time: 16:52)

Now, coming to this saturated fatty acid. As I have already mentioned that, it is, it does not have any double bond closely packed, strong attraction between chains, high melting points, and solids at room temperature. It is a well established fact and world health organization also claims that, if a person is continuously taking a saturated fat or a saturated fatty acid, then he or she will have definitely the cardiac diseases. in with the continues taking of the this saturated fats.

(Refer Slide Time: 17:47)

### Unsaturated fatty acids

- Contain one or more double C-C bonds
- Nonlinear chains do not allow molecules to pack closely
- Few interactions between chains
- Low melting points
- Liquids at room temperature
- Unsaturated fatty acids can occur in a *cis* or *trans* configuration

So, what is the unsaturated fatty acid? It contains one or more double bond. If one double is there, it is mono. If it has more than 1, 2 and 3, that is the polyunsaturated fatty acid. That is, pufa. Non-linear chains do not allow molecules to pack closely. Few interactions are there between the chains and that is reason, it has got a low melting point and liquid at room temperature and unsaturated fatty acid can occur in a *cis* or the *trans* configuration.

(Refer Slide Time: 18:34)

Now, if you see the structure of stearic acid; see here, the carboxylate and straight chain fatty acid. Whereas, in oleic acid, you see, here also it is 18 carbon molecule and here the double bond is present. It is also ending with the carboxylate. So, it starts with the carboxylate and when it is coming 1 2 3 4 5 6 7 8 9 and 10, this double bond is there. See, there is a kink. There is bent to this. That is making the inter property or inter characteristics of the molecule different.

(Refer Slide Time: 19:14)

Now how? If the stearic acid has got melting point of 71 degree centigrade because, it is closely packed molecule. See here, melting point is 71 degree centigrade. In case of oleic acid, it is 13 degree centigrade and in case of linoleic acid, you see here, two double bonds are there and you see the melting point is minus 5 degree centigrade. So, with the number of double bonds, the characteristics and the behavior of the entire molecule is getting changed.

(Refer Slide Time: 20:01)

**Hydrogenated fats**

- Hydrogenation leads to either saturated fats and or trans fatty acids
- The purpose of hydrogenation is to make the oil fat more stable to oxygen and temperature variation (increase shelf life)
- Example of hydrogenated fats: Crisco, margarine
- Unsaturated fatty acids may be converted to saturated fatty acids by simple hydrogenation reaction. The addition of hydrogen to an alkene (unsaturated) results in an alkane (saturated) formation
- A simple hydrogenation reaction is:  
$$\text{H}_2\text{C}=\text{CH}_2 + \text{H}_2 \longrightarrow \text{CH}_3\text{CH}_3$$

If we come to this hydrogenated fat, hydrogenation leads to either saturated fat and or trans fatty acid. The purpose of hydrogenation is to make the oil and fat more stable to oxygen and temperature variation. It also increases the shelf life of product. Now, one of the example of this is, the Crisco or margarine etcetera. Unsaturated fatty acid may be converted to saturated fatty acid by simple hydrogenation reaction. By the addition of the hydrogen, we know that that, alkene can be converted to alkane. If we say the hydrogenation reaction, so this type of reaction is taking place resulting in the hydrogenated fat. Dalda is one of the examples of this hydrogenated product.

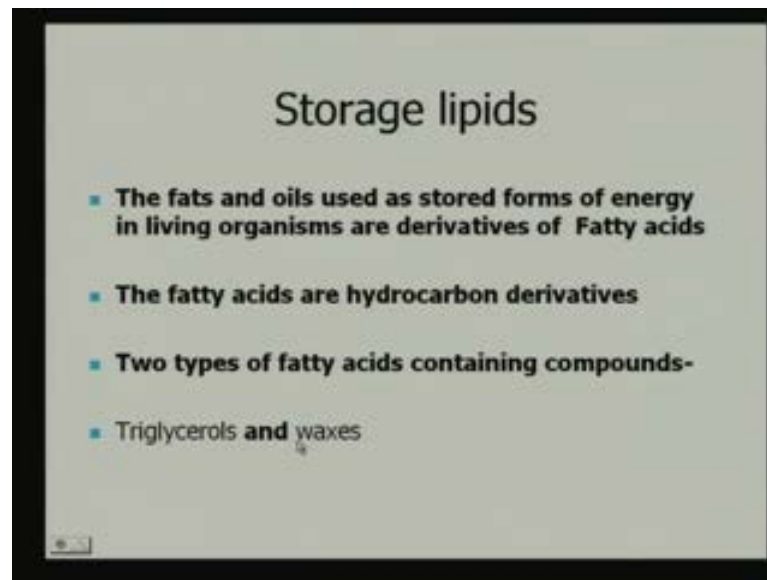

(Refer Slide Time: 21:06)

**Classification**

- Lipids are classified into 2 groups based on structure and function
- storage lipids (neutral)
- structural lipids (polar)

Now, this is, as I have already mentioned about this classification, it is based on the backbone structure of the fatty acid. This fatty acid, this lipid molecule can also be classified based on its biological structure and function. It can be divided into two parts. One is the storage lipid and another is the structural lipid.

(Refer Slide Time: 21:39)

Now, when we are coming to the storage lipid, the fats and oils used in stored forms of energy in living organisms are derivatives of the fatty acids. The fatty acids are hydrocarbon derivatives. Two types of fatty acids containing compounds are there. Triglycerols and waxes are the example of the storage lipid molecule.

(Refer Slide Time: 22:04)

### Properties of fats and oils

- Fats are solids or semi solids
- Oils are liquids
- Melting points and boiling points are not usually sharp (most fats/oils are mixtures)
- When shaken with water, oils tend to emulsify
- Pure fats and oils are colorless and odorless (color and odor is always a result of contaminants) – i.e. butter (bacteria give flavor, carotene gives color)

Now, when we are talking about properties of the fats and oils, fats are solid or semi solids in nature and oils are liquid. Melting point and boiling point are not usually sharp in case of this fats and oils. When shaken, it forms the emulsified product and pure fat and oils are colorless and odorless. Once we are getting some odor or color, we can easily detect that this particular product is contaminated.

(Refer Slide Time: 22:48)

### Waxes

- Simple esters of fatty acids (usually saturated with long chain monohydric alcohols)

*Beeswax* – also includes some free alcohol and fatty acids

*Spermaceti* – contains cetyl palmitate (from whale oil) – useful for Pharmaceuticals (creams/ointments; tableting and granulation)

*Carnauba wax* – from a palm tree from Brazil – a hard wax used on cars and boats

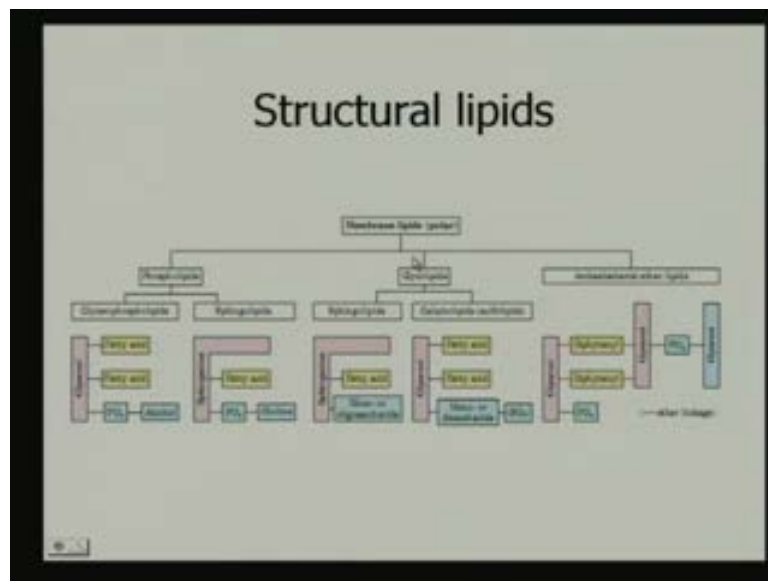

Now, coming to the wax. Wax is the example of simple lipid. Now, it is the simple ester of fatty acid and it has got a very long chain of monohydric alcohol, which is attached to

this, its structure. Now, when it is warm, we are getting a soft form of wax. But, when it is at room temperature, then we are getting a solid mass of wax.

Now, when we see the different forms of these, the wax is present in different biological molecules. Then, we can find that, it is acting as a coating material of many biological molecules. Say for example, it is present in the skin, fur, feather etcetera. In some animals, waxes are also present on the exoskeleton. In case of some insects, it is present on exoskeleton. This particular molecule has got fatty acid, long chain fatty acid and long chain alcohol within its core moieties. It is also present in higher plants and animals too. Now, some of these examples, this beeswax is one of the example of the wax. Now, it is also, this bee wax also contains the fatty acid and some free alcohol within it.

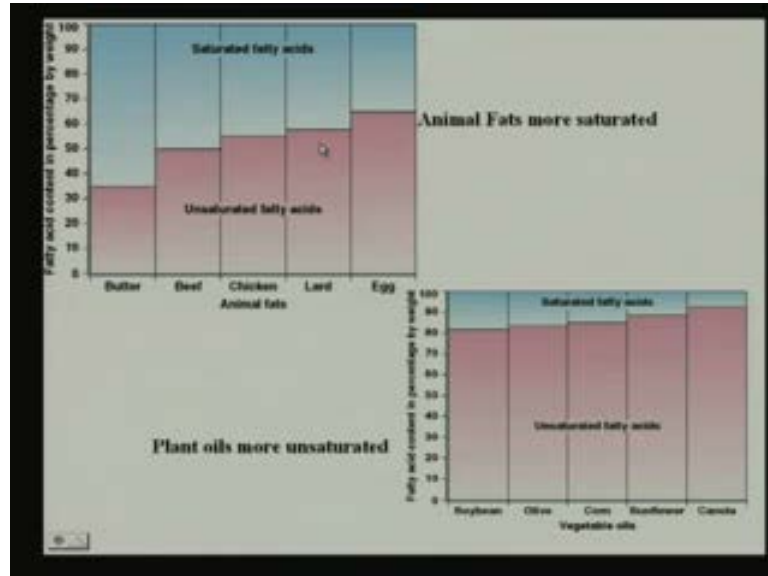

(Refer Slide Time: 24:33)

Now, coming to the structural lipid. If we see the structural lipid, that indicates, the name itself is telling that it is giving the structural support or strength to the membrane of the cell wall of the cell. If we see the membrane lipid, membrane lipid is one of the very important example of where the structural, this lipids are playing a very important and significant role. It can be divided into different parts. Say for example, phospholipid, glycolipid and archaeobacteria ether lipid. So, these are the different composition of this structural lipids, which are mainly present in the cell wall or cell membrane of the cell, of any animal or plant cell. Now, glycerol phospholipid, sphingolipids are the example,

and galactolipid are the example of such type of lipid molecule, where either the glycerol are sphingosine are present as the core moieties.

(Refer Slide Time: 26:04)

Now, I will be coming in details about structure gradually. Now, if we see the sources of different lipid molecules in animals as well as plants, we can find that, in animal system, whatever is the lipid molecule present is mostly the saturated form of lipid molecule. Here, the proportion of saturated versus unsaturated, you see, starting from butter, beef, chicken and animal fat, lard, eggs etcetera, you see, here the proportion of unsaturated fatty acid is much smaller compared to the plant sources. Here, the amount of unsaturated lipids or unsaturated fatty acids is more compared to the animal fat. Here, you see the difference between plant lipid and the animal lipid.

(Refer Slide Time: 27:02)

### Triglycerides: Fats and Oils

Triglycerides are formed from a single molecule of glycerol, combined with three molecules of fatty acid.

The glycerol molecule has three hydroxyl (-OH) groups. Each fatty acid has a carboxyl group (-COOH).

In triglycerides, the hydroxyl groups of the glycerol join the carboxyl groups of the fatty acid to form ester bonds.

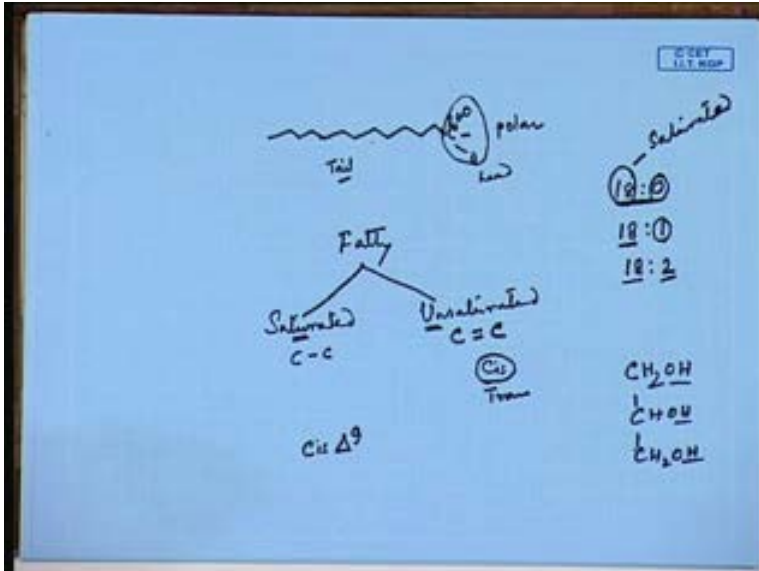

**a triglyceride.**

The diagram shows a vertical rectangular block labeled 'Glycerol' on the left. Three horizontal rectangular blocks labeled 'Fatty acid' are connected to the right side of the glycerol block by lines, representing ester bonds.

Now, coming to the triglycerides. Triglycerides are formed from a single molecule of glycerol. Now, if we see the structure of glycerol, then what we can see, glycerol is the three carbon molecule, CH<sub>2</sub>OH, CHOH and CH<sub>2</sub>OH. This is the glycerol moieties.

(Refer Slide Time: 27:18)

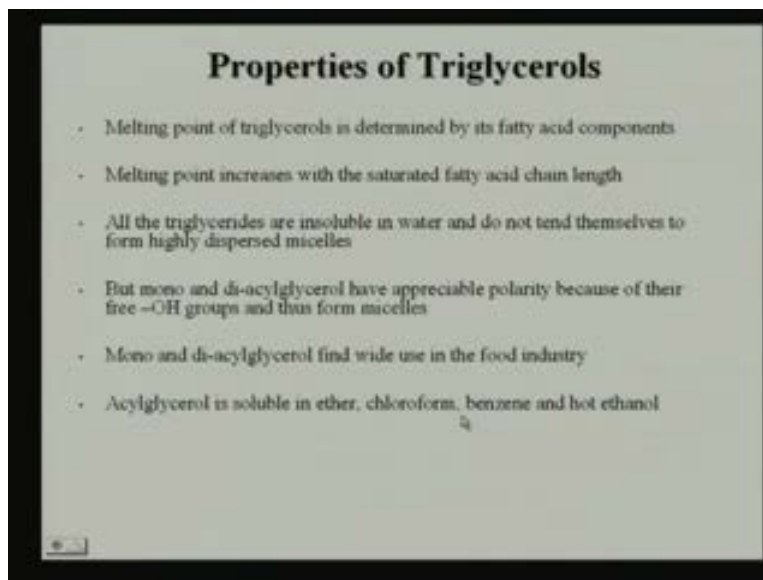

The handwritten notes on a blue background include:

- A diagram of a wavy line representing a hydrocarbon tail, labeled 'Tail', with a circle at the end labeled 'polar head'.
- A tree diagram for 'Fatty' acids:
  - 'Saturated' with 'C-C' and 'C<sub>18</sub>H<sub>36</sub>' written below.
  - 'Unsaturated' with 'C=C' and 'C<sub>18</sub>H<sub>34</sub>' written below.
- A list of saturated fatty acids: '18:0', '18:1', and '18:2', with '18:0' circled and labeled 'Saturated'.
- The glycerol backbone structure: CH<sub>2</sub>OH, CHOH, and CH<sub>2</sub>OH.
- A small box in the top right corner containing 'COPY' and '11.11.2020'.

So, here in triglycerides, a single molecule glycerol is there combined with the three molecules of fatty acid. The glycerol molecules have three hydroxyl OH group within it. Each fatty acid has a carboxyl end. That I have already mentioned that, any fatty acid has got a carboxyl or the polar end within it. So, in triglycerides, the hydroxyl group of

glycerol joins the carboxyl group of the fatty acid to form the ester bond. That means, this hydroxyl group and carboxylic group is getting linked with each other with the ester linkages and they form the triglycerides.

(Refer Slide Time: 28:30)

Now, if we see the properties of the triglycerols, then we can find that the melting point of triglycerols is determined by its fatty acid component. Melting point increases with the saturated fatty acid and its chain length. All the triglycerides are insoluble in water and do not tend themselves to form highly dispersed micelles. But, mono and diacylglycerol have appreciable polarity because of their free hydroxyl group. Thus, they can form micelles structure. Mono and diacylglycerol find wide use in the food industry. Acylglycerol is soluble in ether, chloroform, benzene and also in hot ethanol.

(Refer Slide Time: 29:26)

### Soaps

- Process of formation of soap is known as saponification
- Types of soaps:
  - Sodium soap – ordinary hard soap
  - Potassium soap – soft soap (shaving soaps are potassium soaps of coconut and palm oils)
  - Castile soap – sodium soap of olive oil
  - Green soap – mixture of sodium and potassium linseed oil
  - Transparent soap – contains sucrose
  - Floating soap – contains air
  - Calcium and magnesium soaps are very poorly water soluble (hard water contains calcium and magnesium salts -these are insolubilized soaps)

Now, when I was talking to you about the saponifiable lipid, now soap is one of the example of saponification process. Now, here if we see the types of soap, we can classify that sodium soap, which is an ordinary hard soap. Potassium soap, it is the soft soap, which is used for the shaving purposes. Castile soap, that is the sodium soap with olive oil and green soap, it is the mixture of sodium and potassium linseed oil. Transparent soap, it contains sucrose along with its structure and floating soap, it contains air. Calcium and magnesium soaps are very poorly water soluble in nature. These are the different types of soap molecules.

(Refer Slide Time: 30:23)

### Phospholipids

- The major components of cell membranes: Phosphoglycerides
  - Containing a phosphate group
  - Nitrogenous or non nitrogenous group is also present
  - Structural component of cell
- Phospholipids are generally composed of FAs, a nitrogenous base, phosphoric acid and either glycerol, inositol or sphingosine

glycerophospholipid

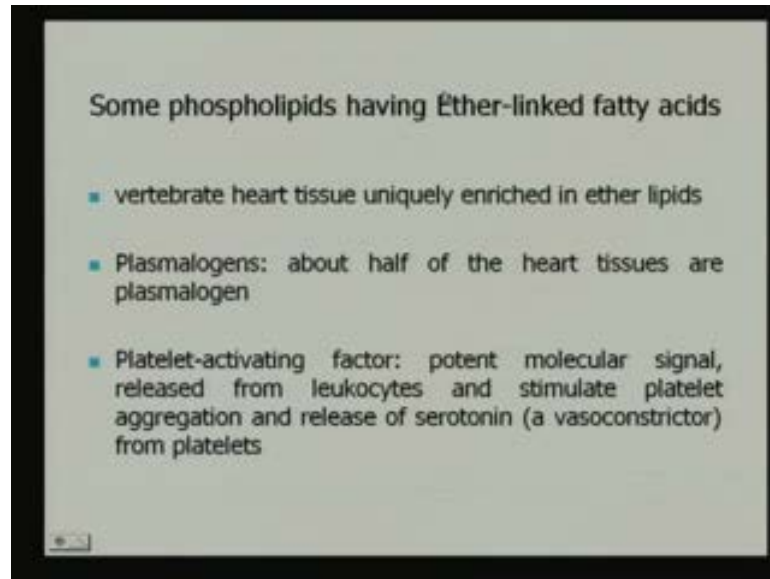

When we are coming to this phospholipid, we can find that the major component, it is one of the major constituent of the cell membrane. Phosphoglycerides contain a phosphate group and nitrogenous or non-nitrogenous group is also present in it. It is the structural component of any cell. Phospholipids are generally composed of fatty acids, nitrogenous base and phosphoric acid and either glycerol, inositol or sphingosine within it. See, I have already talked to you about the glycerol molecule  $\text{CH}_2\text{OH}$   $\text{CHOH}$  and  $\text{CH}_2\text{OH}$ . See, here this, in this core moieties here, this core moieties, say first group is attached with the fatty acid. Second group is also attached with the fatty acid and third group, you see, one phosphate is attached and one x is there.

(Refer Slide Time: 31:31)

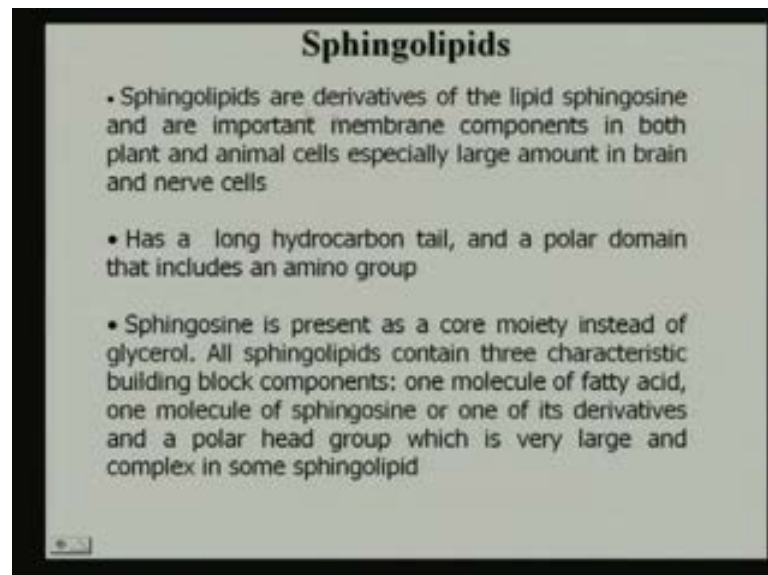

This x may be the precursor for the phospholipids and it may be phosphatidic acid. It may also be phosphatidyl choline or it may be phosphatidyl serine, phosphatidyl ethanolamine and so on. So, this is the core structure and this is the glycerol structure along with this fatty acid hydrophobic tails which are there and to this, this phosphate moieties are attached and to this x group, where this precursor of the phospholipids, phosphatidyl choline, phosphatidyl serine, phosphatidyl ethanolamine any moieties can come and join and form the molecule.

(Refer Slide Time: 32:19)

Some phospholipid, which has the ether-linked fatty acids are there in a living system. Some of the examples are, vertebrate heart tissue is uniquely enriched with this type of ether lipids. Plasmalogens, that is, half of the heart tissues are the plasmalogens. Platelet activating factors are also the example of the ether-linked fatty acid.

(Refer Slide Time: 33:01)

Now, coming to the sphingolipid. Sphingolipids are derivatives of the lipid sphingosine and are important membrane component in both plant and animal cells, especially large amount of brain and nerve cells. So, this particular lipid moieties are mainly present in

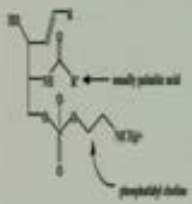

(Refer Slide Time: 35:46)

### Spingomyelin (a ceramide)

The amino group of sphingosine can form an amide bond with a fatty acid carboxyl to yield a ceramide

It is a ubiquitous component of animal cell membranes, where it is by far the most abundant sphingolipid. It can comprise as much as 50% of the lipids in certain tissues, though it is usually lower in concentration than phosphatidylcholine

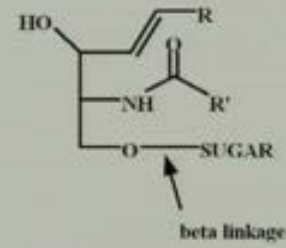

© 2011

Now, coming to this spingomyelin. It is a ceramide. The amino group of sphingosine can form an amide bond with the fatty acid carboxyl group to yield a ceramide. So here, this is the bonding, which is this ceramide. This is the amino group, which is getting bonded. It is ubiquitous component in the animal cell membrane, where it is, by far the most abundant sphingolipid. It can comprise as much as 50 percent of the lipid in certain tissues, though it is usually found in lower concentration than the concentration of phosphatidylcholine, which is present in the cell.

(Refer Slide Time: 36:42)

### Glycolipids

Glycolipids are lipids that contain carbohydrates

beta linkage

polar head is a sugar

Their role is to provide energy and also serve as markers for cellular recognition

© 2011

Similar to that is another type of lipid, which is called as glycolipid. As name itself indicating that, in glycolipid, they contain the carbohydrates moieties within it. That means, sugar moieties are there, which has got linked with the beta linkages. As I have already told you, alpha linkages and beta linkages. So here, it is attached with the beta linkages and polar head group is there for this sugar. Their role is to provide energy and also to act as a marker for cellular recognition. So, this is the major activities of the different types of lipid molecules.

(Refer Slide Time: 37:29)

Now, I will be coming to another type of lipid moieties, which is called as the steroids. Now, the steroid is a typical, a type of organic compound that contains a specific arrangement of four rings, that is joined with each other. That means, if we see the structure of steroid, we can find that, you see, it has been denoted as A ring, B ring, C ring and D ring. Now, if we see A, B and C, then we can find that, this A, B and C ring are cyclohexane ring. Along with this cyclohexane, the D ring, which is attached, is the cyclopentane ring. Now, this ring is also called as perhydrocyclopentano phenanthrene ring. Now, this sterane core of steroid is composed of seventeen carbon atoms bounded together to form a four fused rings. That is, three are cyclohexane, and one is cyclopentane. So that means, this is a very complex water insoluble lipid moieties.

(Refer Slide Time: 39:09)

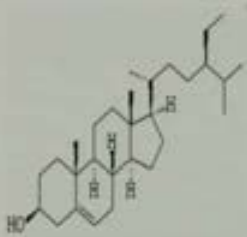

Cholesterol is one of such example of this steroid. Cholesterol has a molecular formula of  $C_{27}H_{46}OH$ . That means, it has got one hydroxyl group which is polar in nature, which makes it soluble in water. This small two atom hydroxyl group structure makes the cholesterol an alcohol. It is the major sterol in the animal tissues. It is amphipathic in nature. That means, on the third carbon of this, first A ring, that hydroxyl group is attached. A polar head, the hydroxyl group at carbon atom number three and a nonpolar hydrocarbon body as long as 16 carbon fatty acid in its extended form. So total, it has got 27 carbon atom and 16 carbon fatty acid is also attached as a alkyl side chain molecule. This is the steroid nucleus. Here, one hydroxyl group is attached on the carbon atom number three.

(Refer Slide Time: 40:51)

### Phytosterols

- **Phytosterols** (also called **plant sterols**) are a group of steroid alcohols, naturally occurring in plants
- Phytosterols occur naturally in small quantities in vegetable oils, especially in corn oil, soybean oil etc.
- They act as a structural component in the cell membrane
- Act as a food ingredient or additive, phytosterols have cholesterol-lowering properties

The image shows a slide titled "Phytosterols" with four bullet points and a chemical structure. The bullet points describe phytosterols as plant sterols, their presence in vegetable oils, their role in cell membranes, and their cholesterol-lowering properties. The chemical structure is a steroid nucleus with a hydroxyl group at C3 and a branched side chain at C17.

While coming to phytosterols, phytosterols is also called the plant sterol. Phytosterols are a group of steroid alcohols, naturally occurring in plants. Phytosterols occur naturally in small quantities in vegetable oils, especially in corn oil, soybean oil etcetera. They act as a structural component in the cell membrane and it also acts as a food ingredient or additive. That is, phytosterols have cholesterol lowering properties. That means, this phytosterols, as I have already mentioned that, cholesterol is present in the animal system and similarly, phytosterol is found in the plant system.

### Ergosterol

- **Ergosterol** a sterol, is a biological precursor (a provitamin) to vitamin D2. It is turned into viosterol by ultraviolet light, and is then converted into ergocalciferol, which is a form of vitamin D
- Ergosterol is a component of fungal cell membranes, serving the same function that cholesterol serves in animal cells
- Ergosterol is also used as an indicator of fungal biomass

The image shows a slide titled "Ergosterol" with three bullet points and a chemical structure. The bullet points describe ergosterol as a biological precursor to vitamin D2, its role in fungal cell membranes, and its use as an indicator of fungal biomass. The chemical structure is a steroid nucleus with a hydroxyl group at C3, a double bond at C5, and a side chain at C17.

When we are coming to this ergosterol, it is also a sterol. It is a biological precursor or the provitamin of vitamin D<sub>2</sub>. It is turned into viosterol by ultraviolet light is then converted into ergocalciferol, which is a form of vitamin D. Ergosterol is component of fungal cell membrane, serving the same function that cholesterol serves in the animal cell. Ergosterol is also used as an indicator of the fungal biomass estimation. Now, this ergosterol, as I have told that, phytosterol is present in a plant and ergosterol is also present. In another type of microbial word, that is the fungus, the filamentous fungus. In any case of this fungal biomass, this ergosterol is present.

**Terpenes**

- **Terpenes** are a large and varied class of hydrocarbons, produced primarily by a wide variety of plants, particularly conifers, and some insects such as termites or swallow tail butterflies
- Simple lipids, but lack fatty acid component
- Formed by the combination of 2 or more molecules of 2-methyl-1,3-butadiene (isoprene)
- Monoterpene (C-10) – made up of 2 isoprene units
- Sesquiterpene (C-15) – made up of 3 isoprene units
- Diterpene (C-20) – made up of 4 isoprene units

CC(=C)C=C  
Isoprene

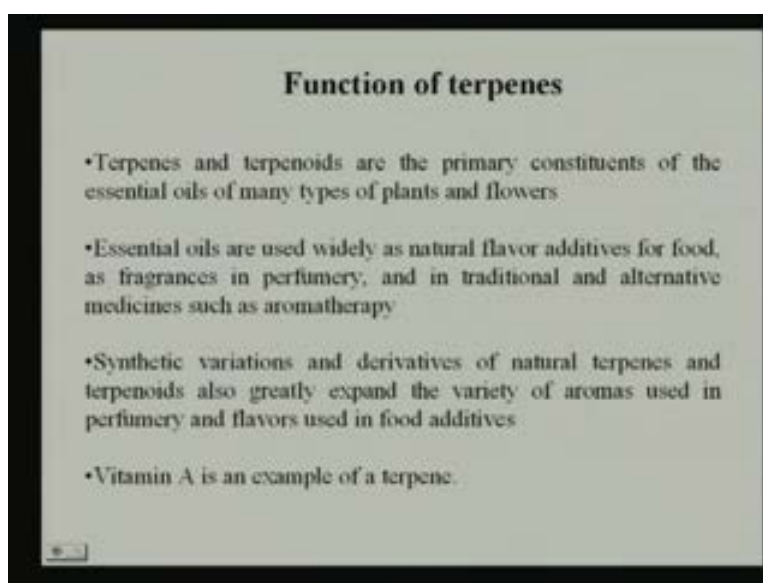

Coming to another component, that is the terpenes. Terpenes are the large and varied class of hydrocarbons produced primarily by the wide variety of plants, particularly coniferous and some insects such as termites or swallow tail butterflies. Now, this is the isoprene molecule. When two such isoprene molecules are coming in association with each other, they form the terpenes. It is a simple lipid but, lack fatty acid component within its core moieties. It forms the combination of two such moieties, that means one isoprene molecule is having five carbon. Now, when two such moieties are associated with each other, so total carbon of carbon atoms present in that structure is C 10. So, monoterpene is the example of that. It is made up of two isoprene units. When three such isoprene molecules are associated, it is called sesquiterpene. When whole isoprene units are there, it is called diterpene terpene and so on.

(Refer Slide Time: 44:23)

If we see the other terpenes, then tetraterpenes are also present, where the total number of carbon atom is 40. Tetraterpenes are not as common as mono, di and triterpenes. It includes the carotenoids, such as beta carotenoid as a precursor of vitamin A and lycopene of the tomatoes. Lycopene is the colour component. It is usually colourful compounds due to highly conjugated systems are there. Polyisoprenoids or polyprenols consist of numerous isoprene adducts, that is 8 to 22 of such and side chain of vitamin K, vitamin E and coenzyme Q are some of the examples of polyisoprenoids molecule.

(Refer Slide Time: 45:17)

If we see the function of the terpene, then terpenes and terpenoids are the primary constituents of the essential oil of many types of plants and flowers. One of the main applications of this terpenoids are in the field of medicine, such as aromatherapy. The synthetic variation and derivatives of natural terpenes and terpenoids also greatly expand the variety of aromas used in the perfumery and flavors, which is used in the food industries or food additives. Vitamin A is an example of a terpene molecule. Now, if we are talking about these particular terpenes, that are gerin oil, limonin, menthol and so on. These are some of the example of this flavor component or constituent which is nothing but, the terpene molecules.

(Refer Slide Time: 46:25)

So, when we are coming to this micelle, the micelle is the aggregate of surfactant molecules dispersed in liquid colloid. Now, as I have already mentioned you that, while discussing the structure, we have seen that fatty acid has got a polar end and a nonpolar tail.

(Refer Slide Time: 46:53)

Now, when a typical micelle in aqueous solution forms an aggregate with the hydrophilic head regions in contact, with the surrounding solvent, sequestering hydrophobic tail region in the micelle centre. Now see, when it is in the aqueous environment, what is happening? This heads, all the heads in the aqueous environment, what is happening? This aqueous, if it is the aqueous environment, then aqueous environment is very good for this hydrophilic molecule to go and it is not at all suitable for the hydrophobic.

So, this is the aqueous. So, hydrophilic in polar head is getting exposed outside and it is just bringing the hydrophobic tail to inside. When such types of associations are there, then it forms the micelle structure. This is the micelle in the aqueous solution. When it is present in a bilayer formation, here is the polar head and nonpolar tails are there. When two bilayer forms are there, see here, the polar head and nonpolar tails. Here also you see, the outer layer, the polar head and nonpolar tails are there. When it forms this type of moieties, it is called the liposome.

(Refer Slide Time: 48:50)

### Function

- Micelle formation is essential for the absorption of fat-soluble vitamins and complicated lipids within the human body
- Bile salts formed in the liver and secreted by the gall bladder allow micelles of fatty acids to form. This allows the absorption of complicated lipids (e.g., lecithin) and lipid soluble vitamins (A, D, E and K) within the micelle by the small intestine
- When surfactants are present above the CMC (Critical micelle concentration), they can act as emulsifiers that will allow a compound that is normally insoluble (in the solvent being used)

Now, the function of these micelles are, the micelle formation is essential for the absorption of fat-soluble vitamins and complicated lipids within human body. Bile salts formed in the liver and secreted by the gallbladder allow micelles of fatty acid to form. This allows the absorption of complicated lipid, that is a lecithin type of lipid and lipid soluble vitamins, that is vitamin A D E and K, within the micelle by the small intestine. When surfactants are present above the critical micelle concentration, they can act as emulsifies that will allow a compound that is normally insoluble in nature.

(Refer Slide Time: 49:47)

### Liposomes

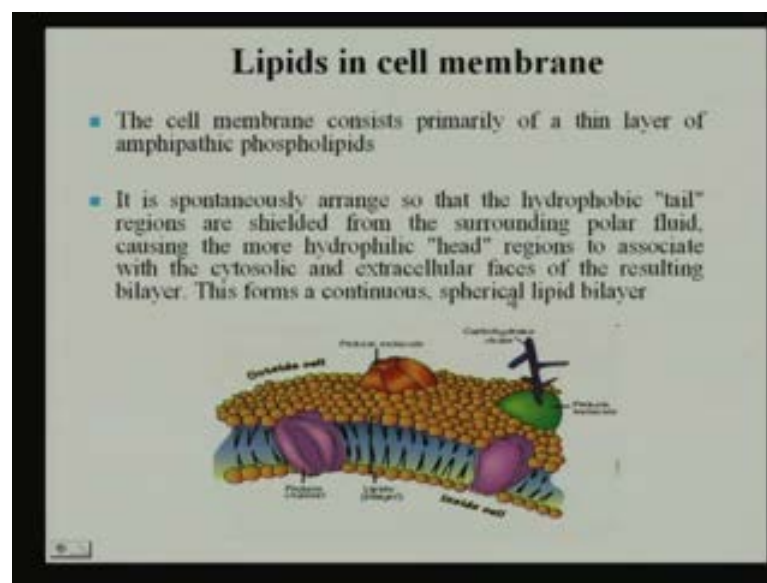

- A **liposome** is a tiny bubble (vesicle), made up of the same material as a cell membrane
- It is a form of micelle
- Liposomes can be filled with drugs, and used to deliver drugs for cancer and other diseases
- Liposomes can be used as carriers for the delivery of dyes, textiles, pesticides for plants, enzymes and nutritional supplements to foods, and cosmetics to the skin

The diagram illustrates a liposome as a spherical vesicle. It features a double layer of phospholipids forming the membrane. The outer and inner surfaces of this membrane are labeled as 'Hydrophilic head', while the central cavity is labeled as 'Aqueous solution'. The liposome is shown in a cross-section, revealing the internal structure.

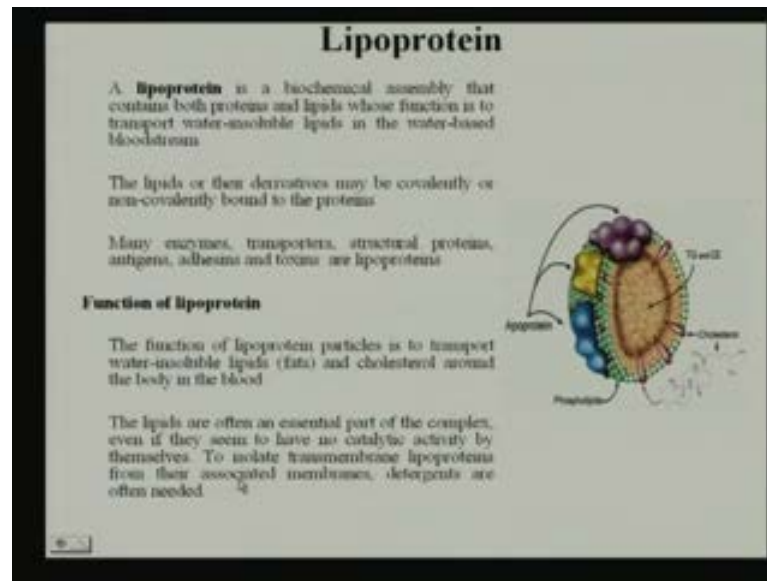

Coming to this liposome. The liposome, as I have mentioned that, the liposome is a tiny bubble vesicles made up of the same material as a cell membrane. It is a form of micelle. Liposomes are filled with the drugs and used to deliver drugs for cancer and other diseases. So here, this aqueous head in the, this is the polar head and this, here also, the polar head and it is the bilayer. It is hydrophobic inside and it helps the drug to transport from one place to another. This type of system is used for drug delivery. Liposome can be used as a carrier for delivery of dyes, textiles, pesticides for plants, enzymes and nutritional supplement to foods and cosmetics to the skin.

(Refer Slide Time: 50:59)

Coming to this lipid in the cell membrane. The cell membrane consists of primarily the thin layer of amphipathic phospholipids molecules. Here, you just see, this lipid bilayer are there. This polar head and here also lipid, this polar heads are there and nonpolar tails are there inside. It is spontaneously arranged, so that, the hydrophobic tail region is shielded from the surrounding polar fluid, causing the more hydrophilic head reason to associate with cytosolic and extra cellular faces of the resulting bilayer. This forms a continuous, spherical lipid bilayer.

(Refer Slide Time: 51:54)

Now, if we come to this lipoprotein, we can find that a lipoprotein is a biochemical assembly that contains the polar proteins. It contains both proteins and lipids whose function is to transport water insoluble lipid in the water based bloodstream. That means, this is, this lipoprotein is mainly acting in the transport of water insoluble lipids from one side to another through the bloodstream. This lipids or their derivatives may be covalently or non-covalently bound with the protein molecule. Many enzymes, transporters, structural proteins, antigen, adhesins and toxins are some of the example of lipoprotein.

Now, if we see the function of lipoprotein, then the main function of lipoprotein particles is to transport water insoluble lipids. That is, fat and cholesterol around the body in the blood. That means, through the bloodstream. The lipids are often an essential part of the complex, even if they seem to have no catalytic activity by themselves to isolate trans membrane lipoprotein from there associated membrane and that is the reason detergents are often used for this purpose.

(Refer Slide Time: 53:46)

Now, if we see the main function of lipids, then we can find that, the main function is the structuring the cell membrane, energy storage, transmission of information in the cell, that is the signal transduction and cellular metabolism, that is the fat-soluble vitamins A D E and K are required for metabolism, which are usually acting as an coenzyme. That means, we can find that lipid is one of such macromolecules which are present and they do not have any catalytic activity. But, it is forming; it is present within the cell system in a conjugated form. It is forming the complete structure with other different macromolecules, which is present in the cell system.

It performs different activities. The major role is the soluble, the polar and nonpolar end which are there. Because of this amphipathic in nature, the polar head and nonpolar tail are getting associated and they are just doing the function of, by exposing the head to the aqueous space and tail away from that particular environment. They do different functions like drug delivery and different lipid **insoluble**, this, the water insoluble transportation of different biomolecules from one side to another. So, with this, today I am concluding the macromolecule which is entirely different. Its character is entirely different from the other macromolecules, which we have already discussed and we have learned. Thank you very much.
