Lecture - 8.3
Wavelets Filters and Fast DWT Algorithm
Part 3/3

Now, when I want to reconstruct...

(Refer Slide Time: 00:15)

Lecture 8.3 References

Perfect reconstruction

Reconstruction is performed using synthesis LP and HP filters, $\tilde{h}[\cdot]$ and $\tilde{g}[\cdot]$ respectively.

- ▶ These filters have to bear relations with the decomposition filters for perfect reconstruction.

Perfect reconstruction conditions

If the filter sequences $h[n]$ and $g[n]$ are finite, i.e., finite impulse response (FIR) LP and HP filters, then perfect reconstruction is achieved if and only if

$$g[n] = (-1)^{1-n} \tilde{h}[1-n], \quad \tilde{g}[n] = (-1)^{1-n} h[1-n] \quad (22)$$

- ▶ These two filters are duals of each other
- ▶ When the analysis and synthesis filters are respectively identical, i.e., $\tilde{h}[n] = h[n]$ and $\tilde{g}[n] = g[n]$,

$$|H(\omega)|^2 + |H(\omega + \pi)|^2 = 2 \quad (23)$$

which is the condition for orthonormal scaling bases or **conjugate mirror filters**

 Arun K. Tangirala, IIT Madras

Discrete Wavelet Transforms 14

So, hopefully, now, you have understood the fast algorithm. I want to reconstruct. Why do I want to reconstruct? Because I want to obtain approximations or details or components of the signal in a particular frequency band.

(Refer Slide Time: 00:34)

So, for examples going back to this figure; suppose I want the signal component in the range 0 to $\omega_{\max}/2$. And, I do not want any other signal component. Then, what I could do is I could take a 1 alone and reconstruct the corresponding part. That is what we have denoted as $\hat{x}_1$ earlier – $\hat{x}_1$ of t . And, likewise, I may be interested only in the frequency range – $\omega_{\max}/2$ to $\omega_{\max}$ or $\omega_{\max}/4$ to $\omega_{\max}/2$ and so on. Or, maybe a certain set of components put together and some. This is the basic idea in signal estimation. When I want to do that, I need to know how to reconstruct. Now, suppose I want to recover the entire signal; I have just decomposed; I should be guaranteed that, if I put together all the coefficients, then I should be able to reconstruct perfectly.

Now, one thing that you should remember in decomposition is when I start off with a naught of n and go up to a certain level; let us say I go up to level 2; in a level 2 decomposition, what I would have at the end is a_2 , d_2 and d_1 . These three sets of coefficients are sufficient to completely recover x . I do not need a_1 . Why? Because a_2 and d_2 have taken birth from a_1 ; they have the complete information for you to reconstruct a_1 . So, the way these coefficients are reported by many software packages is a_2 is stacked... d_2 is stacked next to a_2 and d_1 is stacked next to d_2 .

(Refer Slide Time: 02:41)

Let me just show that to you on the board. So, if I perform a two-level decomposition; then, I would have coefficients a_2 , d_2 and d_1 . This is how one would report. Of course, as a column vector or a row vector, that convention rest with the software package. But, what you should remember is if the signal is of length n , then a_2 – the sequence here would be of length n by 4. Essentially, n by 2^2 and d_2 would be of length n by 4; and, d_1 would be of length n by 2. That is a consequence of down sampling. In arriving at d_1 , we have down sampled ones by factor of 2. In arriving at a_2 and d_2 , a down sample twice, because a_2 and d_2 are coming from a_1 alone. Of course, at level one, I would have a_1 and d_1 . But, a_2 and d_2 are taking birth from a_1 . And further, if I go down; then, a_2 would be decomposed. This is called a wavelet tree – DWT tree. And, I would obtain a_3 , d_3 , and so on; in which case, a_3 would be of length n by 8; d_3 would be of length n by 8 and so on. So, when I report the decomposition – wavelet decomposition at a certain level; if it is a two-level, I would report a_2 , d_2 , d_1 . If it is a three level, I would report a_3 , d_3 , d_2 and d_1 and so on. The total length at any level decomposition will always be equal to the length of this signal. That is the basic idea.

Now, in perfect reconstruction, what I need to be guaranteed is – let us say I look at a three-level decomposition; if I start... If I take the three-level decomposition coefficients – a_3 , d_3 , d_2 and d_1 ; and, I perform the inverse operations. So, what I have done here is I have convolved and I have down sampled. The inverse operations would also involve some kind of filtering; but, it would involve up sampling. And, there are conditions

under which only you can perfectly recover this signal. These conditions are on the filters that are used in reconstructing. That is the basic idea. Whichever level I start with, the moment I am given all the necessary coefficients, I should be able to recover the signal. That is the condition of perfect reconstruction. I avoid all the theoretical discussion here. But, I will give you straight away the condition for perfect reconstruction. Assume that, this h and g are finite in length. Those are familiar with signal processing. We will know that, we are referring to FIR filters – finite impulse response filters, because h and g can be also infinite impulse response filter. There has been... We have never imposed such a restriction on h and g anywhere in our discussion until now.

But, normally, the kind of filters that we use in wavelet analysis are FIR filters. And, for FIR filters, that is, if I perform the wavelet decomposition with FIR filters, then the synthesis filters will have to bare a certain relation with the analysis filters as given by Smith and Banwell and... In fact, more generalization of this is due to Vetter Lee. And, the derivation of this... The proofs of this statement is given nicely in Mallat's book and elsewhere in literature. I recommend that you look through it if you are really interested. But, from a practical view point, what we are interested in knowing is how these synthesis and analysis filters are related. And, these expressions are given in 22. $\tilde{h}$ and $\tilde{g}$ are the synthesis filters. And, g and h as we know are the analysis filters. So, you can see that, $\tilde{g}$ of n ... $\tilde{h}$ is dependent on g ; that is, the synthesis low-pass filter is dependent on the high-pass filter. And, the synthesis high-pass filter is related to the analysis low-pass filter; so, since this low pass is related to analysis high pass and synthesis high pass is related to analysis low pass.

Although we have been using these terms: synthesis and analysis, these two sets of filters play dual roles; which means I could consider $\tilde{h}$ and $\tilde{g}$ as analysis filters. Then, h and g become synthesis filters; or, I can consider h and g as analysis; and, $\tilde{g}$ and $\tilde{h}$ become synthesis filters. So, their roles are reversible; pretty much like what we said in frame theory. We talked about frames and then we talked about dual frames and we said dual frames and frames can play reverse roles. I can call one frame; fix one as a frame and call the other as a dual frame. When the analysis and synthesis filters are respectively identical. So, this condition is for general synthesis and analysis filter. But, if I require that, $\tilde{g}$ equals g and $\tilde{h}$ equals h , then you can show that, these two

conditions can be written nicely in the fourier domain, that is, in terms of the frequency response functions as a single condition given in equation 23. So, now, I do not have $\tilde{h}$ and $\tilde{g}$ and h and g separately. The same h and g that I use for analysis will be used for h and g for synthesis as well. If I do that, what condition should the filter satisfy? Now, we know everything is tied only to one decision, which is that of low-pass filter as long as that low pass filter satisfies this condition. Now, this is a condition that we have seen earlier.

(Refer Slide Time: 09:04)

Lecture 8.3 References

Conjugate mirror filter

Orthonormality of scaling functions and that scaling function should act as a low-pass filter can be stated as constraints on the LP filter $h[n]$

$$\sum_n h[n]h[n+2n'] = \begin{cases} 2, & n' = 0 \\ 0, & \text{otherwise} \end{cases} \quad \text{or} \quad |H(\omega)|^2 + |H(\omega + \pi)|^2 = 2 \quad (5)$$

$$\sum_n h[n] = \hat{H}(0) = \sqrt{2} \quad (6)$$

► Conditions on $H(\omega)$ appears by re-writing the scaling relation in (3) in the Fourier domain as

$$\Phi(2\omega) = \frac{1}{\sqrt{2}} H(\omega) \Phi(\omega) \quad (7)$$

and requiring that $\Phi(\omega) = 1$ for $\phi(t)$ to act as an LP.

The discrete LP filter characterized by the impulse response $h[n]$ is said to be a **conjugate mirror filter**

 Arun K. Tangirala, IIT Madras

Discrete Wavelet Transforma 5

If you recall, this is a condition that we had said is required for orthonormality of these scaling functions. Automatically, h satisfies this. So, you do not have to really do anything. The moment I choose h that corresponds to a scaling function and essentially satisfying equation 5, and I design g according to this relation 14; then, I have the analysis and synthesis filters already. This 14 comes from the fact if you recall that, I want orthonormal wavelet basis. So, to summarize, I choose h as a low-pass filter satisfying equations 5 and 6. That is the conditions of orthonormality and low-pass filter. Then, I choose g such that I get orthonormal wavelet bases according to equation 14. Then, I can use both these filters for analysis as well as synthesis. And, that is the reason they are also known as conjugate mirror filters. So, h and g of course, are known as conjugate mirror filters mostly because of equation 14 that we have seen. But, these conjugate mirror filters also provide perfect reconstruction.

(Refer Slide Time: 10:19)

And now, we have the reconstruction algorithm at the top. So, there are three figures here. At the top, we have the perfect reconstruction algorithm, where you read essentially from here left to right. What I am generally given as you have seen earlier is an approximation coefficient and all the detailed coefficients at that scale and finer scales. So, in this algorithm here, I know a 2 for example, or this a – at the starting a here; and then, the d's at this scale and then the d at the finer scale, and the d at finer scales and so on. So, if I assume that I performed a level l decomposition, then I have a l, d l, d l minus 1, d l minus 2 up to d 1. So, I start with a l and d l up sample. This is intuitively to counter the down-sampling operation that I performed. But, theoretically, you can say that, this is to cancel the aliasing. We have not talked about that; but, the down sampling introduces some kind of aliasing. And, in the reconstruction, you have to cancel the aliasing. So, the up sampling cancels that aliasing. So, I obtain the up sampled sequences of a l and d l; convolve them with the synthesis filters. As we have just discussed, I can choose the synthesis and analysis filters to be identical; add them up; I recover a l minus 1. And then, I have d l minus 1 with me because that is already given to me. Again I up sample them; reconstruct, get a l minus 2 and so on until I reach a naught, which is that a recover this sequence.

Now, what I can do is as I mentioned earlier, I can reconstruct a particular approximation – approximation in a particular frequency band; which is that, I can take a l alone and up sample; and then, that will give me a l minus 1; that is, up sample filter giving me a l

minus 1; again up sample filter and so on until I reach the maximum, that is, the finest scale. When I perform this operation only on the approximation coefficient in a particular band or coefficients in a particular band, what I recover is the approximation corresponding to that frequency band; or, it is the approximation that I have corresponding to that scale. But, that is what it is essentially big A subscript l. And, I can apply this as well to the detailed coefficients; take the detailed coefficients in any band, up sample; or, you can start with d l up sample filter, use the high-pass ((Refer Slide Time: 13:30)) filter; obtain d l minus 1 hat and so on.

Now, I use hats here because ideally to produce a l minus 1, I need both a l and d l. But, here what I am doing is I am throwing away the d l; or, in other words, you can say I am zeroing out the details at level l and only retaining a l. Therefore, I do not get a l minus 1; I get a hat l minus 1. I only get an approximation of a l minus 1. Likewise here ideally, I can take d l minus 1 from what is known to me. But, if I do not want that, then I can approximately construct that from d l and so on with that. So, this is the basic idea in signal estimation. If I want to estimate... If I know that, the main component of the signal is in a particular frequency band, I zero out all the other coefficients – coefficients in all the other bands and then simply perform the reconstruction.

(Refer Slide Time: 14:34)

Lecture 8.3 References

Multiresolution Approximation by example

Consider a signal sequence $\{x[1], x[2], \dots, x[N]\}$ whose MRA we wish to construct. Choose Haar filters $h[n] = \left[\frac{1}{\sqrt{2}}, \frac{1}{\sqrt{2}}\right]$ and $g[n] = \left[\frac{1}{\sqrt{2}}, -\frac{1}{\sqrt{2}}\right]$.

The filtered data sequence is

$$\tilde{a}_1 = \frac{x[1] + x[2]}{\sqrt{2}}, \frac{x[2] + x[3]}{\sqrt{2}}, \frac{x[3] + x[4]}{\sqrt{2}}, \dots, \text{ and } \tilde{d}_1 = \frac{x[1] - x[2]}{\sqrt{2}}, \frac{x[2] - x[3]}{\sqrt{2}}, \frac{x[3] - x[4]}{\sqrt{2}}, \dots,$$

Next, downsample by a factor of 2 to obtain the *scaling* and *detail* coefficients at $j = 1$,

$$a_1 = \frac{x[1] + x[2]}{\sqrt{2}}, \frac{x[3] + x[4]}{\sqrt{2}}, \frac{x[5] + x[6]}{\sqrt{2}}, \dots, \text{ and } d_1 = \frac{x[1] - x[2]}{\sqrt{2}}, \frac{x[3] - x[4]}{\sqrt{2}}, \frac{x[5] - x[6]}{\sqrt{2}}, \dots,$$

Arun K. Tangirala, IIT Madras

Discrete Wavelet Transforma

So, let us look at two examples to conclude the lecture. The first example is more of symbolic; and, the second example is more graphical and numerical. So, let us take a

signal sequence here of length n . And, let us say I want to really perform the DWT or MRA. Let us choose the HAAR filters. The HAAR filters are given as $\frac{1}{\sqrt{2}}$ $\frac{1}{\sqrt{2}}$. That is a low-pass filter. And, g of n is the high-pass filter $-\frac{1}{\sqrt{2}}$ $\frac{1}{\sqrt{2}}$. In fact, you can quickly check that, when I sum up the coefficients here in h of n , what do I get? I get $\sqrt{2}$. So, it satisfies the condition that I had for low-pass filtering. And in fact, you should check that, if I take the fourier transform of this $-\frac{1}{\sqrt{2}}$ $\frac{1}{\sqrt{2}}$, it satisfies the condition, which is $\text{mod } h \text{ of } \omega^2 \text{ plus mod of } h \text{ of } \omega \text{ plus } \pi^2 \text{ is } 2$. So, that exercise I leave it to you. And, you can also see that, the sum of the coefficients of g is 0, which is a requirement for g to be high-pass filter. Remember g of ω at ω equal 0, is nothing but the sum of the time domain sequence. So, therefore, this satisfies all the conditions for generating MRA for computing DWT using orthonormal wavelets and scaling functions.

So, what I am trying to do here is I am showing you what kind of results you would get when you walk through the decomposition algorithm at the first step. So, at the first step, what you do is you would convolve, you would take the sequence and perform filtering. Here the filter is $\frac{1}{\sqrt{2}}$ $\frac{1}{\sqrt{2}}$. When you perform the convolution, it is essentially taking averages of two successive points, because convolution would yield that. It is an FIR filter. So, it is performing averaging, but with a factor of $\sqrt{2}$ here. That is the a_1 that you would get. And, this is a d_1 , which will have successive differences. One – you have averages of two successive points; and, the other containing differences of two successive points.

Now, down sample by a factor of 2; that is, I am going to throw away every other value in a 1 . So, I am going to through away x_2 plus x_3 by $\sqrt{2}$. I am going to throw away x_2 minus x_1 by $\sqrt{2}$ and so on. And, when I do that, I have a 1 and d_1 . Now, quickly what you should notice is; by throwing away a factor of 2, I have not lost any information at all. What do I mean by this? I can start off with a 1 and d_1 and still perfectly recover x_1 , x_2 , x_3 and so on. How do I do that? Pick the first value of a 1 ; x_1 plus x_2 over $\sqrt{2}$; pick the first value of $d_1 - x_1$ minus x_2 over $\sqrt{2}$. And then, do what? Simply perform two operations. Take the average and what would you get? You will get $\sqrt{2}$ of x_1 . If you average the first values in a 1 and d_1 ; simply add them up; you do not even need to take the average; simply add them up; you will get $\sqrt{2} x_1$ divided by $\sqrt{2}$. What have we done? In fact, all I need to do is multiply the first

coefficient with root 2 in a_1 and multiply the first coefficient of d_1 with root 2; add them up; I will get x_1 .

What have I done here? I have convolved a_1 and d_1 with the... In fact, ideally, I should be doing up sampling; but, I am just saying that, I have averaged a_1 and d_1 with h itself; that means, synthesis filter is also the same. h has coefficients $1/\sqrt{2}$, $1/\sqrt{2}$. I take the same coefficient and apply them to a_1 and d_1 . Ideally, I should be up sampling also; but, I am not showing you that operation. So, this is how you can perfectly reconstruct the signal. So, this kind of tells you what you can do.

(Refer Slide Time: 18:50)

Lecture 8.3 References

MRA: Example 1 ... contd.

The original sequence can be still reconstructed with this downsampled sequence:

$$x[1] = \frac{a_1(1) + d_1(1)}{\sqrt{2}}, x[2] = \frac{a_1(1) - d_1(1)}{\sqrt{2}}, \dots,$$

The multiscale approximation can be constructed until a desired level J . The coarsest approximation coefficients are obtained at $J_{\max} = \log_2 N$.

Arun K. Tangirala, IIT Madras
Discrete Wavelet Transform
17

As I said here, you can recover x_1 , x_2 in this fashion and so on.

(Refer Slide Time: 18:58)

Now, let me show you the second example here on a polynomial that is used by Mallat in his book. And, this signal can also be generated using wave lab. In the next lecture, I will show you how to compute this in decomposition and the reconstructions in mat lab. For now, let us understand this decomposition. What I have taken is I have taken this piece-wise regular polynomial or signal and performed a three-leveled decomposition. When I perform three-level decomposition, I have four sets of coefficients: a_3 , d_3 , d_2 and d_1 . And, this plot clearly shows the differing time resolutions. The signal although being shown continuous is actually a sampled sequence available; let us say every sampling interval is 1; then, the sampling interval for d_1 ; or, the time resolution for d_1 will be 2. For d_2 , it would be 4; for d_3 and a_3 , it would be 8.

So, as you can see here, I have 256 points. Here because the sampling interval is 1, the time duration is still 256; but, I have 32 points in a_3 . And, I have 32 points in d_3 ; 64 points in d_2 ; and, 128 coefficients in d_1 . Put together, the total length is still 256. So, if you are looking at signal compression, for example, you would see clearly that, the value of a_3 is quite high compared to the values of d_1 or d_2 . So, what I could do is – in signal compression, I would say I can store only a_3 and d_3 and I can discard d_1 and d_2 . Then, I would achieve a compression factor of 4, because 32 and 32 – 34 coefficients I would store and throw away the other points that I have here, which is 256 minus 64 – 192. So, I have... I would have achieved a compression factor of 4. Of course, it would be a lossy compression. But, that is the basic idea in the signal compression using

wavelets. That is a crude way of compressing; but, that is the basic idea. The refinements that you can perform is – apply a certain threshold; only store significant coefficients; you do not need to discard an entire level, set of coefficients at a certain level; you can apply a threshold at every level and only store the significant coefficients at each level and so on. Those are all the refinements. But, that is a basic idea.

Now, when you look at the right-hand side plot, they are showing the reconstructions corresponding to the coefficients here. So, what we have done here; we have taken a 3 and run it through this reconstruction algorithm here. I have taken only a 3, up sampled, filtered; again, up sampled, filtered and so on. And, I would get this big A 3. And then, I have the big D 3 corresponding to the small d 3; that is, if I were to use only d 3 for reconstruction – the small d 3, I would recover the big D 3. And, an important point to keep in mind is the big A's and D's here – the reconstructed components are all at the same time resolution as the original signal. So, you have come back in time fully in at the same scale at which the signal is available.

What is a difference between – then the signal and these components? They contain different frequency components; that is a point. And, as you can see the d 1 for example here – the reconstructed component in corresponding to d 1 contains only the high frequency blurbs naturally so, because in constructing this big D 1, I have only considered the small d 1, which is in the highest frequency band – $\omega_{\max}$ over 2 to $\omega_{\max}$. And, the high frequency bands will contain all the abrupt changes that you see in the signal. The low frequency ones are slowly changing ones would be contained in the lowest frequency band, that is, in small a 3, or the component of the signal in big A 3. You can see the big A 3 is a nicely smoothened version – smooth version of the signal itself.

(Refer Slide Time: 23:31)

Now, finally, MRA; in fact, this is not exactly MRA; but, in some sense, yes, because... And, in fact, I apologized for the ordering here; the ordering is not right here. What is read as a 1 here should be a 3; and what you see as a 3 should be a 1. So, if I take a 3, then it is the approximation of the signal at scale 2 power 3 or at level 3. When I add d 3 to a 3, then I would get the next level approximation. And then, when I add d 2 and d 3 even, then I would get the next level approximation, which I see here. And, when I add all of these, that is, a 3 plus d 3 plus d 2 plus d 1; then, I would get the signal itself. This is possible because I have used perfect reconstruction filters. That is what is a condition of perfect reconstruction. I take up all the reconstructed components in the individual bands; add them up; I will recover the signal. So, as I said, the numbering here is wrong. This should have been a 3 and then a 2, a 1, a naught. Why the last signal should be called as a naught is because you get the signal back itself. So, that is the small error. And, we will take note of that when I put up the slide for you; that is it.

(Refer Slide Time: 25:13)

So, this has been a lengthy lecture of course. But, one of the key lectures in DWT, which tells you how the DWT is computed; more importantly, how the wavelet filters are designed starting with the scaling functions. Remember we said in CWT that, in CWT, the scaling functions are derived from wavelets; whereas, in DWT, we derived the wavelet from the scaling functions and we generated in particular orthonormal wavelet basis. There exists another route, where one can design biorthogonal wavelet basis; that we will briefly talk about it in the closing lecture on this unit. And, what we have also learnt is a pyramidal algorithm and the recursive relations responsible for that fast algorithm. And then, went through a couple of examples on decomposition and reconstruction understanding the results from a DWT analysis. So, hopefully, you learnt something valuable from this lecture. In the next lecture, I will show you how to carry out all of these in mat lab. Then, we will talk about the choice of wavelets; and, how wavelets are synthesized from these filters themselves. So, that is about it. See you in the next lecture.
