Lecture – 50
Successive over Relaxation (SOR) method

It looks like we had a longer session in the last lecture, so will try to make it slightly lesser this time. To begin with we are looking at advance method which will increase the rate of convergence of our iteration method.

(Refer Slide Time: 00:26)

When we say increase over what we can get with Jacobi method and Gauss-Seidel method and one of the first methods that were proposed is what is known as the successive over relaxation method.

(Refer Slide Time: 00:44)

Improved Convergence Rate: Successive Overrelaxation (SOR)

- The rate of convergence of GS scheme can be improved through overrelaxation, i.e.,

$$x^{k+1} = x^k + \omega \Delta x^k \quad \text{where } \Delta x^k = (x^{k+1} - x^k) \quad \text{and } \omega > 1$$
- Convergence is possible for $0 < \omega < 2$ and SOR scheme with GS can be written as

$$M = D/\omega - E \quad N = (1 - \omega)/\omega D + F$$

resulting in the iteration scheme

$$(D/\omega - E) x^{k+1} = [(1 - \omega)/\omega D + F] x^k + b$$
 or

$$x^{k+1} = (D/\omega - E)^{-1} [(1 - \omega)/\omega D + F] x^k + (D/\omega - E)^{-1} b$$

- As before, we don't do matrix inversion explicitly and write SOR scheme as

$$a_{11}x_1^{k+1} = a_{11}x_1^k - \omega(a_{11}x_1^k + a_{12}x_2^k + a_{13}x_3^k + \dots + a_{1n}x_n^k - b_1)$$

$$a_{22}x_2^{k+1} = a_{22}x_2^k - \omega(a_{21}x_1^{k+1} + a_{22}x_2^k + a_{23}x_3^k + \dots + a_{2n}x_n^k - b_2)$$

$$\vdots$$

$$a_{nn}x_n^{k+1} = a_{nn}x_n^k - \omega(a_{n1}x_1^{k+1} + a_{n2}x_2^{k+1} + a_{n3}x_3^{k+1} + \dots + a_{nn}x_n^k - b_n)$$
- The number of arithmetic operations is not very different from that for Jacobi or GS and for sparse A, it varies as $\sim 6n$

This method is, goes together with Jacobi method and Gauss-Seidel method as almost like a basic iterative method, because it is not very different from those methods. So, the idea of this successive over relaxation is that, in the general case in an iterative method we have some way of determining $x_k + 1$ from x_k and there is an increment, we are in essence incrementing in x_k by Δx_k to get x_{k+1} . We know that in the case of convergent schemes and especially under asymptotic convergence conditions and we are approaching this solution asymptotically from one side.

So, if you are approaching asymptotically then that means, that we are taking steps, but may be not taking as big as step as can be taken and we are taking small steps. So, if you can increase the step size more than what we think it should be, because we are getting Δx_k from the equation and the amount of Δx_k that we get depends on the iteration matrix p and it also depend on x_k . So, that means that Δx_k is not constant, the step size is not constant, but we seem to be every time under estimating that step size. So, is it possible to increase it by factor and thereby over relax it than what we can do and that is the essence of this.

So, suppose we write x_{k+1} equal to $x_k + \omega \Delta x_k$, where Δx_k is what we get using our conversions scheme. So, if you put ω equal to 1 then, we

have no over relaxation. So, we are saying that x_{k+1} is the previous value and whatever your Jacobi method or Gauss-Seidel method praise this Δx_k to be. We are saying that it is only asymptotically approaching and it can be higher. So, can it be higher by a factor ω ? If you say ω is greater than 1 then, you are over relaxing at every step so it becomes a successive over relaxation method.

So, this relaxation methods are by which you can find Δx_k and you are saying that is more than that by certain amount ω when ω is greater than 1, for typical problems where you apply Gauss-Seidel method all though not in all cases, in the case where A is diagonally dominant is good way of saying it. In such a case you can show that ω can be less than 1 and this modification factor will not affect it is property of whether it is converging or diverging.

So, the method will remain convergent as long as ω is between 0 and 2. If it is less than 0 or greater than 2, then it may diverge. So that means, that we can take any value between these and typically when ω is less than 1, you say it is under relaxation. When ω is greater than 1 you say it is over relaxation. So when ω is greater than 1 you are taking a step size which is greater than what should be taken as per the Jacobi method or the Gauss-Seidel method. When ω is less than 1 you are saying that it should be less than what it should be taken what is estimated.

If you are trying to speed up the rate of convergence, speed up the number of steps that are required to get your objective of getting close enough to the true value, then you would like an over relaxation ω to be greater than 1. But if you suspect, for example this Δx_k estimate itself is subject to errors because you are solving a set of equations and you are making assumptions because of coupling or non-linearity or making assumptions about what is the Δx_k ? That is when you are trying to solve non-linear algebraic equation or a set of equations, then you could say for the sake of safety, for the sake of convergence you could say that i will under relax i would not take the full value that is predicted and only take part of the value.

So, then you could say that i will take ω to be between 0 and 1, you will be under relaxing, but here are $Ax = b$ is a linear equation linear algebraic equations and

we do not have to worry about under relaxation. We can definitely use over relaxation and when A is diagonal dominant we can take ω to be anything between 1 and 2 and we can do that over relaxation. So, once you put a value to ω here, then given that you have x^k determined by Jacobi method or whatever method.

So, if you use Gauss-Seidel method, this is equivalent to saying that x^{k+1} equal to Mx^k plus N equal to Mx^k minus $(1-\omega)N$ in that M is $D^{-1}(L + \omega U)$ and N is $(1-\omega)D^{-1}b$. Where, D is the diagonal terms of A and L is the those terms which are below the diagonal and U for the terms which are above the diagonal. So, with this notation for a given $Ax = b$ you can directly find M and N as per the Gauss-Seidel method with this extra factor ω which is added and we take for over relaxation ω to be between 1 and 2 .

So, this will give us an iteration scheme like this. So, now you have $x^{k+1} = D^{-1}(L + \omega U)x^k + (1-\omega)D^{-1}b$ and what we would like to say is that in this case if you put this as $x^{k+1} = Px^k + Q$, this P here is different from the P that you have with Gauss-Seidel method. What it means is that, its convergence rate is affected by the change that you are making and the change that you are making is ω here.

If you take ω to be 1 then this thing will go to 0 and you will have $D^{-1}(L + U)x^k + D^{-1}b$ and you will get back to Gauss-Seidel method. If ω is greater than 1, then you have extra influence of the diagonal elements here and these things here. So, that will mean that you have an iteration matrix, which is different from what you have it is the Gauss-Seidel method and therefore, it will have different convergence behavior.

Now although we are putting it like this in terms of this inverses as before, as in the case of Jacobi method and Gauss-Seidel method, we do not do matrix inversion directly. This whole thing can be written just like we wrote in the Gauss-Seidel method except that, we put this $A_{11}^{-1}(x^{k+1} - \omega(A_{21}x^k + A_{31}x^k + \dots + A_{n1}x^k) - b_1)$ here and then we have this $A_{11}^{-1}(x^{k+1} - \omega(A_{21}x^k + A_{31}x^k + \dots + A_{n1}x^k) - b_1) + \omega(A_{21}x^k + A_{31}x^k + \dots + A_{n1}x^k) + b_1$ play that is all the elements at the previous time step minus b_1 and this whole thing is minus b_1 . So, this is b_1 times ω minus this value and plus this value here.

And similarly for x_2^k it is a 2×2 minus ω times this whole thing. Since we know x_1 as the updated value we make use of the updated value, as for as evaluating as per the successive over relaxation is concerned, we are adding 1 multiplication here. ω times this and then this is we can depending on how it is computed. So, it is either already computed or it is there and this gives a subtraction. So, and then this whole thing is divided by a 1.

So, I can see as a result of this may be 1 or 2 more multiplications per equation and since you have equation here is like that for us pass matrix you have only certain number of non 0 components here. The total number of arithmetic operations to go from step k to step $k + 1$, is not very different from that for Jacobi or Gauss-Seidel method and it varies as may be six n or seven n and like that compare to 5 n for the case are Gauss-Seidel method or Jacobi method.

So, despite putting this extra factor here, you are only increasing the number of arithmetic operations by n in this. So, it becomes and instead of factor of 5 you now have factor of 6 or 7 depending on how you compute it here. That makes it readily implementable as easily implementable, as the Gauss-Seidel method or Jacobi method. So, in a way it is a small extension to the Gauss-Seidel method.

Just as Gauss-Seidel method can be considered as a small extension to the Jacobi method. So, this is all in the same family with the same kind of approach solution. Now what does it did to the convergence rate? We have said that as long as this ω is between 0 and 2, whether it diverges; converges is not changed. Convergence is assured, but at what rate? Now the rate of convergence is depends as before on the spectral radius of the new iteration matrix.

(Refer Slide Time: 11:35)

Improved Convergence Rate: Successive Overrelaxation (SOR)

- The rate of convergence of SOR depends on its spectral radius, as before
- The optimal relaxation factor, when A is symmetric and positive definite, is given by
$$\omega_{opt, GSOR} = 2/[1 - \rho^2(P_{Jac,opt})]^{0.5}$$
- The spectral radius for the optimal relaxation factor is given by
$$\rho_{GSOR} = \omega_{opt} - 1$$
- For the case of the Laplace equation with Dirichlet boundary conditions, the spectral radius of the Jacobi iteration matrix is $\cos(\pi/M)$; therefore ω_{opt} for the GS-SOR is
$$\omega_{opt} = 2/[1 + \sin(\pi/M)] \approx 2(1 - \pi/M)$$
- Hence the spectral radius at optimum relaxation is given by
$$\rho_{GSOR} = 2(1 - \pi/M) - 1 = 1 - 2\pi/M$$
- For large M and in the asymptotic limit, the number of iterations required to reduce error by an order of magnitude varies as $n^{0.5}$ and that the total number of arithmetic operations required to reduce error by a decade varies as $n^{1.5}$, compared to n^2 for GS
- In the general case, ω_{opt} changes with A and one may need to estimate it numerically!

So, that is involving all this omegas and it cannot be computed for the general case. For any case of either that may be resulting from the discretization like this, but for the specific case of a symmetric and positive definite.

So, then optimum value of omega, so the idea is that this omega varies between 1 and 2 for the case of over relaxation, but the rate of convergence does not vary monotonically between 1 and 2, it typically goes through a minimum or the number of iterations needed to reduce a residual by factor of 10. That value which was saying is asymptotically convergence rate. It reduces as omega is increased it goes to a minimum and then it starts again coming back up. So that means, there is an optimum value of omega at which for a given a matrix and for a given SOR method.

There is in optimum value for which you will have the least number of iterations steps need to reduce the residual by factor of 10. So, it will have the highest convergence rate. What the optimum value is not known apriori, but for the specific case of when a is symmetric in positive definite, then the optimum value for Gauss-Seidel method of SOR where Δx_k is determined as per the Gauss-Seidel method is given by this expression here. So, this is 2 divided by 1 minus 1 minus rho square root of 1 minus rho square and

what is this rho? it is rho is a spectral density of the optimum value of optimum iteration matrix think.

So, where the Jacobi s o r is optimal, when this is known when the optimal value of omega is known, then the spectral radius is defined as omega optimal minus 1. So, this is a spectral radius. For the optimal value of Gauss-Seidel SOR and this it depends on the spectral radius of this.

For the specific case of Laplace equation with Dirichlet boundary conditions, you know all this things. We know the Eigen values and we know everything about it and the spectral radius of the Jacobi iteration matrix is cosine pi by m therefore, the optimum value of omega, the over relaxation parameter for the Gauss-Seidel SOR scheme is given by 2 by 1 plus sine pi m which is roughly equal to 2 times 1 minus pi by m and therefore, the spectral radius is given by this minus one. So, that gives us 1 minus 2 pi by m.

Now, how does this is compared with the previous values? For the previous value for the g s scheme we had rho g s as 1 minus pi square by m square.

(Refer Slide Time: 15:21)

Convergence Analysis of the Basic Iterative Schemes

- In iterative methods, $Ax = b$ is solved as $x^{k+1} = Px^k + q$ $k \geq 0$
- Define error, ϵ , as $\epsilon = \bar{x} - x$ where \bar{x} is the exact solution, i.e., $A\bar{x} = b$ and $\bar{x} = P\bar{x} + q$
- At the k^{th} iteration, we have, $e^k = \bar{x} - x^k$ and $Ax^k = b^k$ and $x^{k+1} = Px^k + q$
- The residual at the k^{th} iteration can be evaluated as $\bar{b}^k = b - b^k = b - Ax^k$: if residual is zero, the solution has converged
- For error reduction, through subtraction, we get $e^{k+1} = Pe^k$
- Thus, at the end of m iterations, we have, $\epsilon_m = P^m \epsilon^0$
- For convergence, $\rho(P) < 1$ where $\rho(P)$ is the spectral radius of iteration matrix P and is given by $\rho(P) = \max \{ |\lambda_i| \}, 1 \leq i \leq n$ where λ_i are the eigenvalues of $P_{n \times n}$.
- For central differencing of the Laplace equation in 2-D with Dirichlet boundary conditions, with uniform spacing in x and y and having $M \times M = M^2$ no of grid points, the spectral radius of the iteration matrix with the Jacobi scheme is given by

$$\rho(P_J) = \cos(\pi/M) \approx 1 - \pi^2/2M^2 \quad \text{for large } M$$
- For the GS scheme,

$$\rho(P_{GS}) = \cos^2(\pi/M) \approx 1 - \pi^2/M^2 \quad \text{for large } M$$

What do we have here? We have $1 - \frac{2}{m}$ and what is significant is that in the case of the spectral radius for Gauss-Seidel it is $\frac{1}{m}$ and here it is $\frac{2}{m}$ and what is m ? m is the number of divisions in the x direction and n the number of equations is the number of divisions in the x direction times the number of divisions in the y direction because that gives you the total number of grid points.

So, in the case where the number divisions in the x direction and y direction are the same, this m is equal to square root of n , where as in the case of Gauss-Seidel method without SOR m is you had m^2 here so, it is proportion to m . Now what does that mean? That for large m this $\frac{2}{m}$ is smaller than $\frac{1}{m}$ so that means that, and the spectral radius here is $1 - \frac{2}{m}$. So, this value is higher than the spectral radius is smaller. When spectral radius is smaller the rate of convergence is faster.

So, for large values of m therefore we can expect the successive over relaxation method of the Gauss-Seidel think to be faster than, what it is for the simple Gauss-Seidel method. So, for large value of m and in the asymptotic limit, the number of iterations require to reduce error or residual by in order magnitude varies as square root of n , where n is the number of equations or number of grid points and the total number of arithmetic operations required to reduce error by a factor of 10 varies as, $n^{1.5}$ or enter power 1.5 and this value varies as n^2 for Gauss-Seidel method so, that means that the arithmetic number of multiplications or divisions, is reduce from constant times n^2 to constant times $n^{1.5}$ or square root of n^3 .

How significant is it? If you take million grid points then n^2 is million square. So, 10^{12} and $n^{1.5}$ is million times square root of million. So, that is 10^9 . So, that is 10^9 . So, that means, that instead of taking 10^{12} number of multiplications you are taking 10^9 number of multiplications. So, that is multiplicative factor of 1000.

So that means that, s o r method is almost 1000 times faster than the non SOR Gauss Seidel method. So, that is a kind of computation advantage we can get, if we were using

the optimal value of omega. Optimal value of omega is known only for set in special cases.

If you want to find out for the true case then you have to do much more and you have to know the all the Eigen values, and the determination of Eigen values for a general matrix itself will take n^3 number of mathematical operations so that means that, we cannot look at we cannot say that let us take the matrix and let us find the Eigen values and then try to choose try to find the best optimal value all that is not possible because Eigen value determination is take itself will take n^3 number of operations. So, that is why only for certain class of problems under certain cases we know it is a convergence rate and we know that it can converge very fast by significant margin compares to the Gauss-Seidel method.

So, in a general case the optimum value of omega changes with α , with the matrix. So, I may need to estimate numerically. So, that is you do for 50 equations and you see by how much by what factor the residual has decreased for a given value of omega. For example, you take omega to be 1.5 and now you do another 50 with omega equal to 1.6 and see whether that residual reduction factor has increased or decreased. If their residual reduction factor rate is decreased, that is; if it has taken the amount of reduction is more than what you had with 1.5 so then that means that may be you can go to 1.7 and then you keep on going like that until you hit the reverse trend.

So, that is now you take 1.8 and you find that it has not reduced in the 50 iterations by as much as it has reduce with value 1.7. Then the optimal values between 1.7 and 1.8, now you take you do another 50 iterations with 1.75 and then try to locate that kind of thing and then you can finally, get an estimate if not the exact value you can get an estimate value of this and then use that value to continue to drive the residual down to you are decide value.

So, that is how you can make use of this. But all this is in a way theoretical because it takes certain number of iterations before you can get into the asymptotic convergence limit and it is under the asymptotic convergence limit, will you have good success with the determination of the optimal value.

So, the overall margin may not be like 1000 fold it may be like 10 fold it may be like 5 fold, but still it is definitely worth it. So, SOR method is a simple extension of the Gauss-Seidel method and for the class of Laplace type of equations, Parson type of equations, diagonal dominant conditions it is it can be use very quickly very effectively to improve the rate of convergence.

In the next lecture we look at other methods having different kinds of philosophies for increasing rate of convergence over these basic methods.

Thank you.
