**Lecture – 17
Quantitative analysis – I**

We meet once again, greetings to you. And yesterday I had started explaining the quantitative analysis by spectrophotometry.

(Refer Slide Time: 00:32)

QUANTITATIVE ANALYSIS BY SPECTROPHOTOMETRY

1. METHOD DEVELOPMENT

In principle any coloured solution can be subjected to chemical analysis by spectrophotometry. Numerous reagents react selectively with non absorbing species to give products that absorb strongly in the ultraviolet and visible regions. A vast literature exists which detail reactions of this type.

Typical inorganic reagents include: thiocyanate ion for Fe, Co and Mo.

Hydrogen peroxide for Ti, V, Cr

Iodide ion for Bi, Pd, Td

Organic chelating agents: DDTC for Cu, Dithiozone for Pb, 1,10-Phenanthroline for Fe, DMG for Ni etc.

We had completed our analysis, and I mean our studies on instrumentation, and then I had as discussed with you about how we are going to develop a quantitative analysis method by spectrophotometry. I had shown you this technique this slide also, quantitative analysis by spectrophotometry. And how we develop a color system using different organic reagents or inorganic reagents etcetera.

(Refer Slide Time: 01:05)

Typical method development procedure involves:

- i) Determination of the wavelength for maximum absorption .
- ii) Optimization of the experimental variables for completion of the reaction. These include: pH, reagent concentrations, temperature, stability of the coloured product, effect of high electrolyte concentrations, stoichiometry of the complex etc.

And then I had explained to you a typical method development procedure, that is to determine the lambda max and then to determine the other experimental variables for the optimum color development of the reaction.

(Refer Slide Time: 01:40)

- iii) Preparation of the calibration curve and
- iv) Evaluation of the interfering substances, matrix effect, and other ionic species.
- v) Determination of molar absorptivity, Sandell sensitivity, statistical evaluation of the bias.
- vi) Applications in diverse matrices.

So, these things included pH reagent concentration and a temperature stability of the colored product and effect of high electric electrolyte concentration stoichiometry of the complex etcetera, you know that is typical method development.

And then we had discussed about the preparation how to prepare the calibration curve, evaluation of the interfering substances matrix effect and other things this I had already explain to you earlier. And we sometimes it is important to determine the molar absorptivity or sandell sensitivity, that is and statistical evaluation of the bias. And then applications in diverse matrix also are important because spectrophotometry is basically a matrix dependent technique. So, any change in the matrix will always lead to slight differences in the absorption and absorbencies. And then the calibration curve may go little here and there therefore, it is important to test the method every time we have a change in the matrix.

So, this slide also, I had shown you and then we are discussing about the simultaneous spectrophotometric analysis.

(Refer Slide Time: 02:46)

SIMULTANEOUS SPECTROPHOTOMETRIC ANALYSIS

Two dissimilar chromophores having different $\lambda_{\max}$ and ϵ if present in a given mixture can be analysed if their absorbances are additive.

The procedure involves measurement of the total absorbance of the mixture at both $\lambda_{\max}$. Then two simultaneous equations can be written ,

$$C_1(\epsilon_1)_{\lambda_1} + C_2(\epsilon_2)_{\lambda_1} = A_{\lambda_1}$$
$$C_1(\epsilon_1)_{\lambda_2} + C_2(\epsilon_2)_{\lambda_2} = A_{\lambda_2}$$

The equations are solved for C_1 and C_2 .

So, here what I said they the means there are there is only one component to be determined in a given analysis. We do not have a problem in the because we can develop a method or a use a development based on the previous slides, but suppose there are 2 substances, which will react with the same reagent. Because basically spectrophotometry is the where the science of measurement has color. So, 2 if there are 2 substances which you colored a complexes then the absorbance will become additive it.

(Refer Slide Time: 03:40)

So, I was assuming that, let us assume that there is a some analyte A which reacts with a reagent, to give you a complex AR, and with a lambda max. It is specific lambda max and suppose I have another component B and then the it reacts with the same reagent R to give you a complex BR and this maybe these 2 colors. These 2 colors are different, but if both of them are present in the same system.

Then we will be seeing both the colors. Now if you represent the other observances in a given a system, that is absorbance versus concentration. The complex of AR maybe having a lambda max like this. Because a spectrum like this and complex of BR, I mean this is for AR and complex BR may have a peak something like this. This is BR. So, any measurement of the sample containing both AR and BR would be the sum of this as well as the other one the absorbance of this plus this.

So, the actual absorbance curve may look something like this and go like this. When both when both AR and BR are present. This is for the lambda max of AR. Same thing is true with respect to lambda max of BR. If this is at lambda 1 and this is at lambda 2. Lambda 2 if I measure absorbance this is a lambda 1, lambda 1 this is at lambda 1. Now there is similar thing will happen and I get a curve something like this. And this one will be at lambda 2. So, any measurement either at lambda 1 or lambda 2 would be the sum of the absorbance, would be the sum of absorbance of AR and BR. This is the problem you

may be making measurements, but you will be measuring the sum of the absorbance of both AR and BR at any wavelength.

Now the question is can we solve out it, this is the problem and determining both AR and BR. Otherwise what I have to do is remove them from the matrix by some other means like solvent extraction, precipitation, filtration and things like that, I have AR determining A and similarly make a procedure for removing the B removing the A and make the determination of BR. Then you can have the analysis, but you can make use of a little mathematics here, and that is by using the simultaneous determination. So, in simultaneous spectrophotometric analysis, what we do is we recognize that there are 2 dissimilar chromophores having different $\lambda_{\max}$. And if they are having different $\lambda_{\max}$ having different colors then the molar extension coefficient also will be different.

So, we set up 2 equations, that is at λ_1 $C_1 \epsilon_1 + C_2 \epsilon_2 = A_1$ plus $C_2 \epsilon_2$ would be the sum of A at absorbance at λ_1 . $C_1 \epsilon_1$ actually it should be ϵ_1 there is an error and $C_2 \epsilon_2$ $C_1 \epsilon_1$ actually λ_2 would be a λ_{10} . So, the equations are solved for C_1 and C_2 . So, if you we have we know they have we have C_1 and C_2 as 2 concentrations and absorbance, we have 2 equations 2 equations and 2 unknowns should be you should be able to sort out the concentrations using a little bit of algebra.

(Refer Slide Time: 09:40)

So, theoretically if the given matrix contains, if theoretical if the given matrix contains more than 2 substances, which will give AR BR n and CR, then can I setup up a 3 3 equation system, where similar thing can be sorted bias can be sorted out and then I can determine 3 unknowns also like, this theoretically any number of things can be done, but there is a practical problem with the this approach, what is a practical approach the absorbance lambda max of the 2 substances should be separated by at least 30 nano meters if I had to apply this method to a fair degree of accuracy.

So, this is what I was telling you normally 3 component system people do and people have tried, but more than 3 becomes a little trickier, then it may not be worthy time and effort and many to do such a such as an analysis.

(Refer Slide Time: 10:56)

DIFFERENTIAL OR EXPANDED SCALE

In spectrophotometry the analog scale varies from zero absorbance to 100% absorbance. The latter is an artificial requirement. Therefore when reference solution transmits more radiant energy than another standard, scale expansion techniques can be used to increase the precision. Three cases result:

- High absorbance method.
- Trace analysis method.
- Maximum precision method.

So, now we go to another aspect of how to determine the substances at very high or very low concentrations. This also I had explained to yesterday I am going to do it in a slightly more detail now, because quite often we come across situations where we do not want to dilute a sample or 2 within 0.2 to 0.8 or absorbance. Sometimes we do we do the concentration of the substance is so, less that it may not be worth make concentrating it between 2 and 0.8 absorbance which is the normal absorbance level for all spectrophotometric methods.

So, I can sight you an example of gold. Yesterday I did that the in gold analysis people do not want to dilute and waste. So, if the color is a very high you know that according to

relative concentration error system error principle the error also will be more. So, what can I do if I want to determine a highly colored substance? And the same thing is true in case of body fluids. In body fluids what happens, we normally have a system where the sample maybe very less. Suppose somebody wants to analyze sodium in brain fluid or in the lead in kidneys, it becomes very difficult because you cannot have too much of the sample, a very small quantity of the sample will be there, and if I take that do some pretreatment and then do the analysis.

The absorbance value will be very low. So, the again the error will be very high at low concentration also. This we have studied when we studied the beer lamberts law. So, I am to attend to such situations, a simple calorimeter which does not have the presence creating said hi and computer etcetera, I have still not required you can still make the analysis in a better way. So, what do we do the analogue scale in the spectrophotometer? You know we know that if we choose absorbance, it varies from 0 to 2. That is the minimum is 0 maximum is 2. If I do the transmittance the same scale should be calibrated from 100 to 0. So, 0 transmittance corresponds to maximum absorbance. So, it will be important for us.

So, an analogue scale varies from 0 to 100 percent absorbance that is two absorbance in absolute scale. So, the letter is an artificial requirement. So, when solution reference solution transmits is more radiant energy, and then another standard then scale expansion technique can be used. We had stopped here. In the last class there is there are 3 ways of dealing with this. One is high absorbance method another is trace analysis method and third is maximum precision method.

(Refer Slide Time: 14:42)

So, let us see what it entails. Look at it now. I have drawn a simple scale analogue scale of a colorimeter. You can see here that the scale in and I have put 4 cases here. 3 cases and the tau 1 2 3 and 4 are there. So, what is happening in this case is the ordinary method has a scale of 0 to 100 on the top. So, I need to analyze a sample which is giving me an absorbance between 20 to 30 percent. So, blank case always around 100 percent reference. And the sample is somewhere between 20 and 40 percent of transmittance.

So, what I do here, so here if the sample is having very low. What I do is I take I want to limit my range to 20 to 40 percent or maybe 35 percent, because my sample maximum contains 35 percent transmittance. So, what I will do is I increase the decrease the light. So, that absorbance is maximum around 2 35 percent is adjusted mechanically to a value of 2. And that comes the remaining 20 percent will be also be expanded by the same method, but it will be somewhere between 40 50 to 60. And any sample in between these 2 would be between 20 and 35 would be measuring between 0.2 and 0.8 absorbance. And it will be showing me a better accuracy. So, this is known as high absorbance method.

Another method is supposing my sample is very dilute sample. So, what I will do is suppose it is about 80 percent transmittance and my sample is somewhere here blank is somewhere here I had just a 100 percent and this 20 percent and 30 percent I have just it know 0 level. So, any sample in between these 2 standard will the scale is expanded from

here to here. That is 0 to I will say about 35 percent. So, this is known as stress analysis method, because the sample is highly transparent here and the error if I measure without any adjustment it will be very high.

So, I am expanding the scale from here to here between let say between 90 80 70 75 percent to 0 percent transmittance. So, this is another way of dealing with substances which are very valuable very small quantity of pure substance available. And transmittance is very low. Now there may be some substances, where I have to adjust it is neither be neither at high absorbance nor at low absorbance. And then what I, but I need the very high accuracy. So, what I will do is, I select this 30 percent as 0 percent and by mechanical means by allowing more light and 40 I adjust it to 100. Anywhere in between can be more accurately described where the concentration can be increased you know and analyzed properly. So, this is known as maximum precision method.

So, there are 3 systems even the put for they have the luxury system is you can choose either this or this or this depending upon the maximum precision required for the analysis.

(Refer Slide Time: 19:06)

DERIVATIVE SPECTROSCOPY

In derivative spectrophotometry spectra are obtained by plotting the first or higher order derivative of the absorbance with respect to wavelength as a function of wavelength.

In a derivative spectrum the ability to detect and to measure minor spectral features is considerably enhanced. The enhanced spectral features can distinguish between very similar spectra and follow subtle changes in a spectrum.

Derivative spectrophotometry is also quite useful for the simultaneous determination of two or more components in mixtures. Absorption spectra of the analyte can be extracted from turbid solutions. Partially overlapping peaks can be resolved by using derivative spectroscopy.

So, now I go to another utility of a spectrophotometer. Now what I need is suppose I have an absorbance spectrum something like this. This is absorbance this is concentration.

(Refer Slide Time: 19:20)

So, if I plot this normally, we expect a peak and peak with lambda max something like this. Then it is very easy for us to find out this is the length wavelength. So, I know where to take the measurement where very absorbance response is optimum.

Now, suppose sometime the color is not very well defined. This is when the color is defined well; that means lambda max is precise. Now suppose the figure is something like this. We do not know whether to choose this peak or this peak or this peak. And whether the difference between this and this could it be an instrument noise, we do not know. In such cases the spectrum so vague that it is very difficult for us to decide where the lambda max difficult to determine the lambda max.

So, what to do now? Answer is go for derivative spectrum. So, what happens in derivative spectroscopy? We required the spectrophotometric delta and scan it and then by plot the spectrum first. Then we can plot the first order or higher order derivative of the absorbance with respect to wavelength as a function, of the length; that means, $\frac{dA}{d\lambda}$.

So, if you plot $\frac{dA}{d\lambda}$ versus λ let us see what happens. In a derivative spectrum the ability to detect and measured minor spectral features is considerably enhanced. See the enhanced spectral features can distinguish between very similar spectrum and follow a subtle change in a spectrum. And it is also useful for the simultaneous determination of 2 or more components. If the lambda max is very near.

Now absorption spectra of the analyte can be extracted also from turbid solutions. This is also another very important advantage when we want to do a derivative spectroscopy. So, partially overlapping peaks also can be resolved very well by using derivative spectroscopy.

I am going to show you a derivative spectrum, shortly the, but before that let us see some examples.

(Refer Slide Time: 23:02)

Examples:

- i) Determination of trace amounts of Mn and Zn in mixtures by complexation with 5,8-dihydroxy - 1,4 - naphthoquinone.
- ii) Tryptophan, tyrosine and phenyl alanine contain aromatic side chains with $\lambda_{\max}$ in 240 - 300 nm region. These sharp peaks are not apparent in spectra of typical protein preparations but observed in first and second derivative spectra.
- iii) Derivative methods are widely applied to pharmaceutical preparations and to vitamin mixtures.

What is happening we want to determine trace amounts of manganese and zinc in mixtures by a complexation with 5 8 dihydroxy 1 4 naphthoquinone. This is an organic reagent it reacts with manganese and zinc to give you colored substances.

Second example is tryptophan tyrosine and phenyl alanine these are the amino acids they contain aromatic side chains with $\lambda_{\max}$ between 240 and 300 nanometers. I have explained to you earlier whenever you are doing this chemical UV spectrophotometry, that in benzene ring aromatic systems the peaks are not very sharp. So, the sharp peaks are not apparent in the spectra of typical protein preparations, but they are also observed in first time, but observed very clearly in first and second derivatives spectra. Then for in pharmaceutical applications definitely there will be a very good utility upset substances. So, here I am showing you the absorbance spectrum the first one is what bottom one.

(Refer Slide Time: 24:17)

Look here, I have a peak which is very vague. And it looks as if it has only one lambda max, and the curve is not very well characterized, there is A. Now look at dA by lambda absorbance, first derivative the same peak how it is showing 1 2 3 4 5 and then one trough here and then lambda max extra. So, suppose I do second time d A square by d lambda square. Then what happens I see the lambda max should be negative, the same peaks get converted into negative peaks, but much sharper 1 2 3 4 5 6, so many other things.

(Refer Slide Time: 25:47)

PHOTOMETRIC TITRATIONS

Photometric titrations are useful for locating the equivalence point of a titration provided the titrant or titrand or one of the reaction products absorbs the radiation. The titration curve is a plot of the absorbance corrected for volumetric changes as a function of the titrant. The end point is obtained by extrapolating the linear portions of the curve.

Photometric titrations can be automated to record a fixed absorbance or by taking the second derivative.

So, this is how the utility of derivatives spectra can be employed to exactly assess; where is the λ_{max} for different colored system. So, we will also discuss about photometric titrations.
