**Lecture – 20**  
**Chemistry of Group 2 elements**

I once again welcome you to MSB lecture series on main group chemistry let me begin my talk today on group 2 elements. Group 2 elements are known as alkaline earth elements this group consists of beryllium, magnesium, calcium, strontium, barium and radium and the electronic configuration of alkaline earth elements is  $NS 2$  that is valence electrons; that means, we have 2 electrons in the valence shell as a result the group oxidation state is plus 2 and as expected being the first element beryllium differs from other elements owing to its smaller size. In fact, beryllium resembles more of aluminum than magnesium and calcium and that is about diagonal relationship between beryllium and aluminum I will discuss those aspects later.

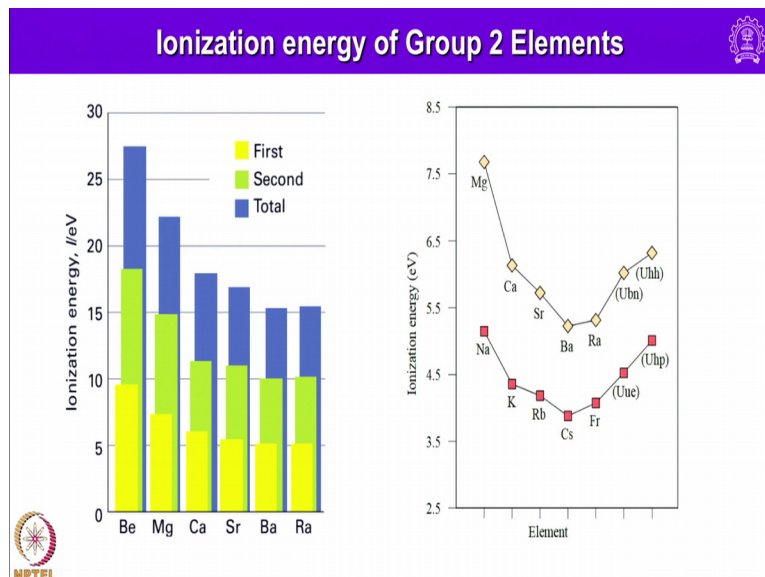

And atomic and ionic radii are smaller than those of group one elements of course, here one electron is added to the same shell and nuclear charge is also increased as a result one can expect the atomic and ionic radii of alkaline earth metals smaller than the corresponding group one elements. The alkaline earth metals are named after their oxides the alkaline earths whose names were berilia, magnesia, lime, strontia, and barita respectively for beryllium, magnesium, calcium, strontium and barium.

These oxides are basic when combined with water; that means, these oxides when they are reacted with water they give hydroxides the basic solution as a result they are called as basic oxides, earth in these elements is referred to earlier essentially for non metallic substances earlier the term earth was added since they were insoluble in water and resistant to heating.

And of course, these properties are shared by these oxides and hence they are called alkaline earth metals and they readily form  $M^{2+}$  ions since the group oxidation state is plus 2 and as expected  $M^{2+}$  ions are smaller than  $M$  atomic and ionic radii increases down the group as the size increases. This is the periodic trend we are familiar with and ionization enthalpy decreases down the group, first ionization enthalpies are higher than

those of the corresponding group one elements this is again following the same expected periodic trends.

(Refer Slide Time: 03:19)

And second ionization enthalpies are higher than the first ionization enthalpies for all alkaline earth metals you can see here the ionization energy of group 2 elements are shown here. For example, you can see first ionization energy is much higher and the second ionization energy is shown here and overall the ionization energy of all alkaline earth metals are shown in this plot and you can see here the first ionization energy or ionization enthalpy or of all alkaline earth metals are much higher than those of alkali metals or group one elements I already mentioned why.

So, then hydration enthalpy, this hydration enthalpy decreases down the group due to the increase in the ionic size, as the ionic size increases down the group charge to size ratio also decreases as a result what happens hydration enthalpy that depends heavily on the charge to size ratio decreases due to the increase in the ionic size and decrease in the charge to size ratio as a result one can expect the trend in this fashion.

(Refer Slide Time: 04:43)

For group, due to the larger size group 2 elements are more extensively hydrated compared to group 1 elements for example, if you see a magnesium chloride is  $6\text{H}_2\text{O}$ ; that means, it has 6 water molecules similarly calcium chloride can take up to 6 water molecules if we compare these things with sodium chloride or potassium chloride they do not form hydrates. So, that is the difference between group 1 and group 2 elements and similar to group 1 metals, group 2 metals are also silvery white in color, soft, but harder than group 1 elements. The hardness relatively more hardness compared to group 1 elements comes because of the availability of 2 electrons for metal bonding strong electropositive property is shown by group 2 elements and this trend increases down the group.

(Refer Slide Time: 06:31)

Properties of Group 2 Elements						
	Be	Mg	Ca	Sr	Ba	Ra
Metallic radius/pm	112	150	197	215	217	220
Ionic radius, $r(M^{2+})$ /pm						
(coordination number)	27(4)	72(6)	100(6)	126(8)	142(8)	170(12)
First ionization energy, $I$ /(kJ mol <sup>-1</sup> )	900	736	590	548	502	510
$E^\ominus(M^{2+}, M)$ /V	-1.85	-2.38	-2.87	-2.89	-2.90	-2.92
Density, $\rho$ /(g cm <sup>-3</sup> )	1.85	1.74	1.54	2.62	3.51	5.00
Melting point/°C	1280	650	850	768	714	700
$\Delta_{\text{hyd}}H^\ominus$ /(kJ mol <sup>-1</sup> )	-2500	-1920	-1650	-1480	-1360	-
$\Delta_rH^\ominus$ /(kJ mol <sup>-1</sup> )	321	150	193	164	176	130

All these properties are displayed here whatever I said so, far. So, let us look into the properties of group 2 elements and the trends whatever I said can be clearly seen here in the metallic radius, metallic radius as expected it is increasing from beryllium to radium and ionic radius also should increase and it is increasing with beryllium showing 27 picometer. Whereas, radium showing 170 picometer and first ionization energy is decreasing as the valence electrons are moving farther from the nucleus ionization of those electrons would be rather easy that you can see here that is also reflected in the reduction potential here.

Reduction potential you can see here the trend and the density is given and melting point also decreases down the group and enthalpy also decreases and all these properties are according to the periodic trends one should expect by looking into the trends seen along rose and also down the group. Let me tell you little about alkaline earth metals and who discovered and as I mentioned all alkaline earth metals are silvery white in color.

(Refer Slide Time: 07:54)

**Who Discovered ALKALINE EARTH ELEMENTS**

						
Beryllium	Magnesium	Calcium	strontium	Barium	Radium	
						
Louis Nicolas Vauquelin Beryllium 1798	Joseph Black Magnesium 1755	Humphry Davy Calcium and Barium 1808 Strontium 1808	Adair Crawford Strontium 1790	William Cruickshank Strontium 1790	Marie Curie Radium 1898	Pierre Curie

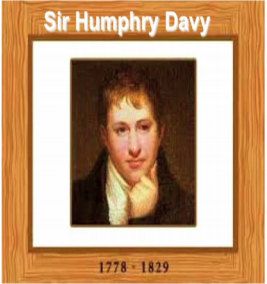

NPTEL

So, you can see here Beryllium, I have shown here Beryllium, Magnesium turnings I have shown Calcium, Strontium little gold color is there freshly sublimed one and Barium and Radium is radioactive. Beryllium was discovered by Louis Nicolas Vauquelin in 1798 and Magnesium was discovered by Joseph Black in 1755 and Humphry Davy.

In fact, he has contributed significantly to the understanding and growth of chemistry especially alkaline earth metals and alkali metals and alkaline earth metals. In fact, he is responsible for discovering and isolating in the pure form many elements that I will be discussing in the next slide and he is responsible for discovering calcium, barium and strontium. Strontium was collectively together discovered by Crawford and Cruickshank in 1790 and later it was isolated in its pure form by Humphry Davy and Marie Curie and Pierre Curie they discovered radium in 1898.

(Refer Slide Time: 09:01)

**Who Discovered ALKALINE EARTH ELEMENTS**

**Born:** 17 December 1778, Penzance, United Kingdom  
**Died:** 29 May 1829, Geneva, Switzerland  
**Known for:** Electrolysis, Al, Na, K, Ca, Mg, Ba, B, Davy lamp  
**Discovered:** Potassium, Calcium, Sodium, Boron, Barium  
**Michael Faraday was his assistant**

And of course, as I mentioned Humphry Davy's contribution is remarkable he just lived for 51 years and he is known for the electrolysis and also giving the method of isolation of and discovery of elements such as aluminum, sodium, potassium, calcium, magnesium, barium, boron and also he is well known for his safety lamp also known as Davy lamp for people who work in the mines.

(Refer Slide Time: 09:38)

**Occurrence**

- Beryllium occurs naturally as the mineral beryl,  $\text{Be}_3\text{Al}_2(\text{SiO}_3)_6$
- Magnesium is the eighth most abundant element in the Earth's crust and the third most abundant element dissolved in seawater
- It is commercially extracted from seawater and the mineral dolomite  $\text{CaCO}_3 \cdot \text{MgCO}_3$
- Calcium is the fifth most abundant element in the Earth's crust but only the seventh most common in seawater due to the low solubility of  $\text{CaCO}_3$

So, let us look into the occurrence of alkaline earth elements beryllium occurs naturally as the mineral beryl important ore of beryllium or important source of beryllium with

composition  $\text{Be}_3 \text{Al}_2 \text{SiO}_3$  6 times and magnesium is the 8<sup>th</sup> most abundant element in the Earth's crust and the third most abundant element dissolved in sea water it is commercially extracted from sea water and the mineral dolomite is nothing, but a combination of calcium carbonate and magnesium carbonate in 1 is to 1 ratio and calcium is the 5<sup>th</sup> most abundant element in the earth s crust, but only the 7<sup>th</sup> most common in sea water due to the low solubility of calcium carbonate.

(Refer Slide Time: 10:20)

**Occurrence** 

- Ca is a major component of biominerals, such as shells and coral**
- Calcium, strontium, and barium are all extracted by electrolysis of their molten chlorides**
- Radium can be extracted from uranium-bearing minerals although all its isotopes are radioactive.**

And of course, Calcium is a major component of bio minerals such as shells and coral and calcium, strontium, and barium all are extracted by electrolysis of their corresponding molten chlorides.

(Refer Slide Time: 10:46)

**Extraction of group 2 elements**

- ❑ Beryllium is extracted by heating beryl with sodium hexafluorosilicate,  $\text{Na}_2\text{SiF}_6$
- ❑ Magnesium is the only Group 2 element extracted on an industrial scale; magnesium, calcium, strontium, and barium can be extracted from the molten chloride.
- ❑ Calcium is extracted by electrolysis of the molten chloride, which is itself obtained as a by product of the Solvay process for the production of sodium carbonate.
- ❑ Sr is extracted by electrolysis of molten  $\text{SrCl}_2$  or by reduction of  $\text{SrO}$  with Al
- ❑ Barium is extracted by electrolysis of the molten chloride or by reduction of  $\text{BaO}$  with Al

Radium can be extracted from uranium bearing minerals such as pitch blend all its isotopes are radioactive and Beryllium is extracted by heating beryl with sodium hexafluorosilicate that is  $\text{Na}_2\text{SiF}_6$  and Magnesium is the only group 2 element extracted on an industrial scale and magnesium, calcium, strontium and barium can be extracted from the respective molten chlorides very similar to the process employed in the extraction and isolation of sodium from sodium chloride.

Calcium is extracted by electrolysis of the molten chloride which is itself obtained as a byproduct of solvay process for the production of sodium carbonate and strontium is extracted by electrolysis of molten strontium chloride or by reduction of strontium oxide using aluminum very similar to thermite process and barium is extracted by electrolysis of the molten chloride or by reduction of barium oxide with aluminum; that means, essentially we have 2 methods at our disposal to extract strontium either from molten halides or from the corresponding oxides.

(Refer Slide Time: 11:51).

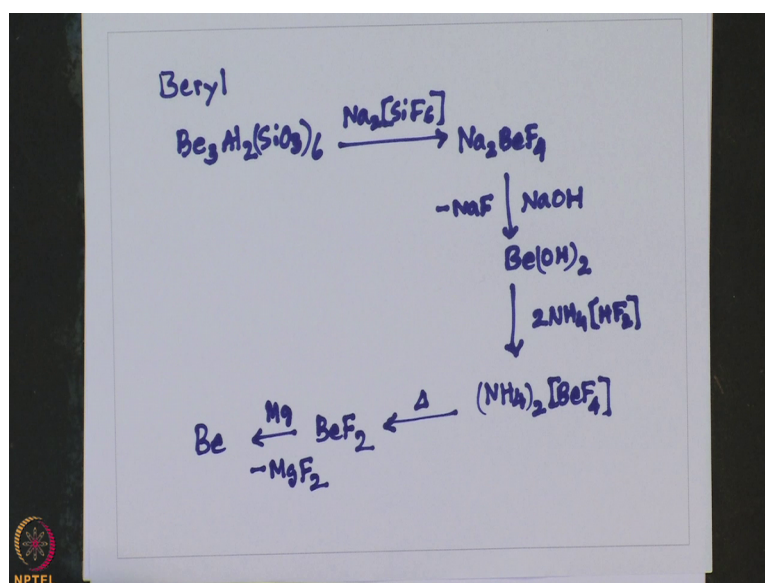

**Extraction of group 2 elements**

- ❑ All the isotopes of radium are radioactive. They undergo  $\alpha$ ,  $\beta$  and  $\gamma$  decay with half-lives that vary from 42 minutes to 1599 years.
- ❑ Radium was discovered by Pierre and Marie Curie in 1898 after painstaking extraction from the uranium-bearing mineral pitchblende
- ❑ Pitchblende is a complex mineral containing many elements: it contains approximately 1 g of Ra in 10 t of ore and the Curies took three years to isolate 0.1 g of  $\text{RaCl}_2$

So, when it comes to radium all isotopes of radium are radioactive they undergo alpha, beta and gamma decay with half life that vary anywhere between 42 minutes to 1599 years for some of their radioactive isotopes and radium was discovered by Pierre Curie and Marie Curie in 1898 after painstaking extraction from the uranium ore Pitchblende and in fact, Pitchblende is a complex mineral containing many elements it is a besides uranium it is a source of many trace elements and also some of the radioactive isotopes of some of the heavier elements and it contains approximately 1 gram of radium in 10 tons of ore and in fact, Curies together took nearly 3 years to isolate 0.1 gram of radium chloride from pitchblende. So, let me the extraction method of beryllium starting from Beryl.

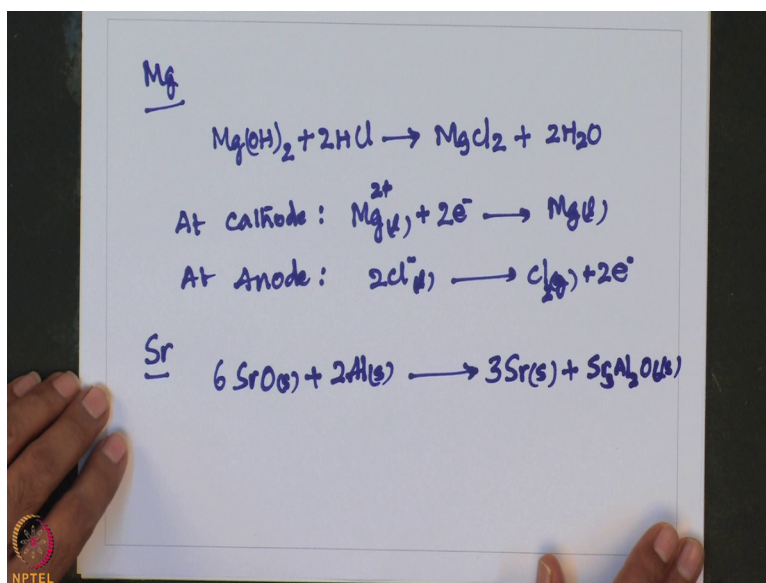

(Refer Slide Time: 12:57)

So, as I said beryl is nothing, but  $\text{Be}_3 \text{Al}_2 \text{SiO}_3 6$  times so, first it has to be treated with hexafluorosilicate sodium hexafluorosilicate. So, it gives  $\text{Na}_2 \text{Be F}_4$ . So, it acts as a (Refer Time:13:36) agent and then this is stated with sodium hydroxide leads to the formation of sodium fluoride and  $\text{Be OH}$  will be separated beryllium hydroxide and on treatment of beryllium hydroxide with this salt gives beryllium tetra fluoride this one on heating gives beryllium fluoride.

So, this beryllium fluoride on reduction with magnesium gives pure beryllium through the formation of magnesium fluoride. So, this is the method used for the extraction of beryllium starting from beryl. So, let me give the extraction method in used in the case of magnesium as I said in case of magnesium one can use molten magnesium chloride, molten magnesium chloride and; that means, preparation of magnesium chloride involves the treatment of magnesium hydroxide.

(Refer Slide Time: 15:11)

With HCl essentially a neutralization process giving the salt and water so, in molten electrolysis at cathode, at Anode (Refer Time: 16:10) of chloride takes place and this is for magnesium the similar method in case of strontium and barium as well in case if we have oxide one can use aluminum of course, here to initiate the formation of aluminum oxide that is highly exothermic first reaction needs. So, this method one can conveniently use in case of barium as well.

So, other method of molten will be similar to this reaction now let us look into the flame test we are familiar with flame test in case of alkali metals, similarly in case of alkaline earth metals calcium imparts brick red color whereas, strontium imparts crimson red and barium imparts characteristic apple green color to the flame and with this let me begin the discussion about the chemical reactivity of group 2 elements of course, when we are looking to the reactivity we follow this sequence.

(Refer Slide Time: 17:40)

## Chemical Reactivity of Group 2 Elements

### Reactivity

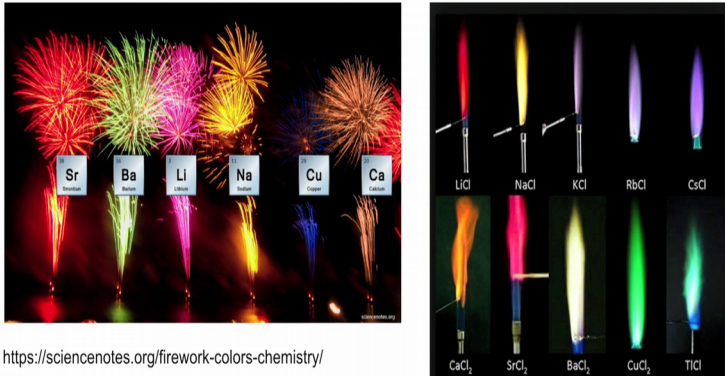

- ❖  $H_2$
- ❖ Air (Oxygen)
- ❖ Water
- ❖ halogens
- ❖  $N_2$
- ❖ reducing nature
- ❖ behavior in liquid  $NH_3$

Let us look into first reaction with hydrogen to form hydrides and then with oxygen to form oxides and maybe with other chalcogens to form the corresponding chalcogenides and the interaction with water and then halogens and nitrogen and other reagents and then it is reducing nature and also behavior of alkaline earth metals in liquid ammonia.

(Refer Slide Time: 18:04)

## Flame Test

<https://sciencenotes.org/firework-colors-chemistry/>

<https://www.pinterest.com/explore/chemistry-teacher/>

So, this is the flame test you can see here. So, calcium strontium and barium all I have shown and.

In fact, because of these vibrant colors they are also used in fireworks.

(Refer Slide Time: 18:18)

**The anomalous properties of beryllium**

- Generally forms covalent compounds such as beryllium halides:  $\text{BeCl}_2$ ,  $\text{BeBr}_2$ ,  $\text{BeI}_2$ , and the hydride,  $\text{BeH}_2$ .
- Tendency to form complexes, with the formation of molecular compounds such as:  $\text{Be}_4\text{O}(\text{O}_2\text{CCH}_3)_6$ .
- Hydrolysis (deprotonation) of beryllium salts in aqueous solution, forming species such as  $[\text{Be}(\text{H}_2\text{O})_3\text{OH}]^+$  and acidic solutions.
- Hydrated beryllium salts tend to decompose by hydrolysis reactions, where beryllium oxo- or hydroxo salts are formed, rather than by the simple loss of water.
- The oxide and other chalcogenides of Be adopt structures with the more directional (4,4)-coordination structures.

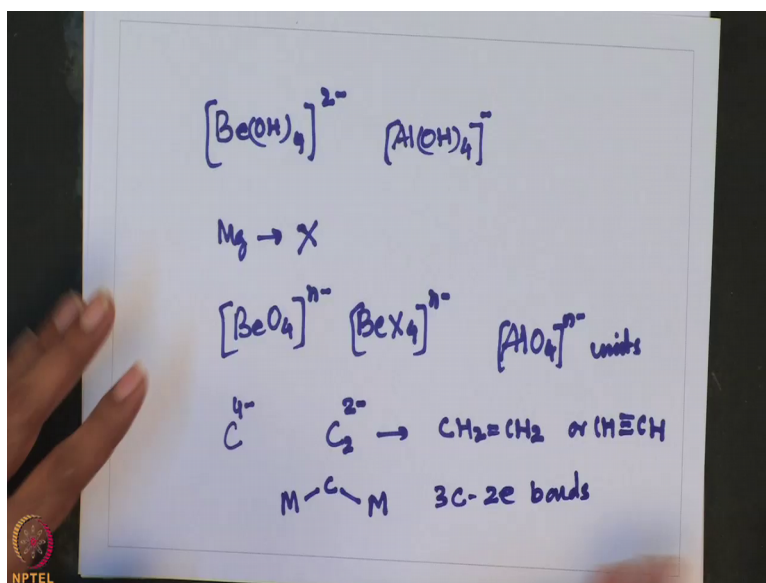

So, before I proceed to consider the reactivity of alkaline earth metals let us look into the difference in the properties of beryllium from the rest of the elements and; that means, the anomalous properties of beryllium should be looked into and let me discuss those properties generally beryllium forms covalent compound such as beryllium halides  $\text{BeI}_2$ ,  $\text{BeBr}_2$ , beryllium iodide and also with hydrogen it forms covalent hydride  $\text{BeH}_2$  and they have a tendency to form complexes because of larger hydration enthalpy with the formation of molecular compounds such as beryllium acetate hydrolysis of beryllium salts in aqueous solution leads to the formation of species such as  $[\text{Be}(\text{H}_2\text{O})_3\text{OH}]^+$  plus acidic solutions and hydrated beryllium salts tend to decompose by hydrolysis reactions where beryllium oxo and hydroxo salts are formed rather than by the simple loss of water.

So, that is the specialty of beryllium and the oxide and other chalcogenides of beryllium adopt structures with more directional coordination structures; that means, essentially they form some coordination compounds very similar to transition metal coordination compounds having preferably 4 coordination. So, beryllium forms many stable organometallic compounds as well including dibethyl beryllium, diethyl beryllium and di butyl beryllium and also it forms beryllioses similar to ferrocene; that means, bis cyclopentadienyl beryllium compound and of course, since I am devoting a few lectures for the organometallic chemistry of main group elements that time I will be elaborating more about the synthesis and stability and structural aspects and both

beryllium and aluminum form covalent hydrides and halides the analogous compounds of other group 2 elements are essentially ionic in nature.

The oxides of beryllium and aluminum are amphoteric whereas, the oxides of rest of the group elements are again basic this is also the trend very similar to what we saw in case of lithium in the presence of excess of hydroxide ions beryllium.

(Refer Slide Time: 20:55)

And aluminum form tetrahydroxy species like Be OH 4 times 2 minus of course, aluminum forms similar soluble hydroxide no equivalent chemistry is observed for whereas, magnesium does not show any of these properties and both elements form structures based on linked tetrahedra. So, beryllium forms structures built from minus and Be X4 x minus tetrahedral and aluminum also forms numerous aluminates and alumino silicates containing Al O4 n minus units.

So, this shows the similarities in the reactions and properties of beryllium with aluminum and both elements form carbides that contain C4 minus ion of course, in carbides these ions will be there and which on hydrolysis are reaction with water produce methane the other group 2 carbides contain essentially C2 2 minus ion and produce ethylene this essentially gives ethylene or acetylene of course, those things I will discuss later when the corresponding carbides are treated with water and alkyl compounds of beryllium and aluminum are electron deficient compounds that contain bridges; that means, essentially this is nothing, but 3 centered 2 electron bonds. So, this is quite common in case of alkyl

beryllium and aluminum compounds and they undergo association to form one dimensional chain.

So, I will be elaborating later about the more details about this one, let us now continue with the chemical reactivity of group 2 elements smaller size compared to alkaline metals you should remember alkaline earth metals have smaller size compared to alkali metals.

(Refer Slide Time: 23:23)

**Chemical Reactivity of Group 2 Elements**

- Smaller size compared to alkali metals; strongly hydrated; high lattice energy
- Be has different chemistry compared to Mg, Ca, Sr, Ba and Ra
- Free  $\text{Be}^{2+}$  does not exist; all its compounds are covalent or contain solvated ions such as  $[\text{Be}(\text{H}_2\text{O})_4]^{2+}$
- Many of the salts are less soluble in water;  $\text{K}_2\text{SO}_4$  is soluble not  $\text{CaSO}_4$  and  $\text{SrSO}_4$
- Be is a rare element;  $\text{Be}_3\text{Al}_2\text{Si}_6\text{O}_{18}$  (Beryl)

And they are strongly hydrated and they have high lattice energy compared to group 1 elements and in fact, beryllium has a different chemistry compared to it is heavier congeners free beryllium 2 plus ion does not exist all its compounds are covalent or contain solvated ions.

(Refer Slide Time: 23:47)

Such as yes; that means, it is very difficult to isolate free beryllium 2 plus ion many of the salts are less soluble in water  $K_2SO_4$  is soluble many of the group 2 salts are less soluble in water  $K_2SO_4$  or  $Na_2SO_4$  if you take they are soluble in water whereas,  $CaSO_4$  or strontium  $SO_4$  are insoluble. In fact, that trend increases down the group. In fact, most of the barium salts are insoluble and beryllium is a rare element and its ore is beryl  $Be_3Al_2Si_6O_{18}$  of course, let me stop here in my next lecture I will be continuing the chemistry of main group 2 elements and begin my lecture with group 2 hydrides, have a pleasant inorganic chemistry reading until then.

Thank you.
