So, we have seen so far that if you have a differential equation of the form  $M(x,y) dx + N(x,y) dy = 0$ . So, this is the first order differential equation, if you have a differential equation in this form, then we have seen that the condition that this differential equation is an exact differential is that  $\frac{\partial M}{\partial y} = \frac{\partial N}{\partial x}$ . And if this condition is satisfied then what you have here is an exact differential and it can be solved very easily and we have seen how to solve it.

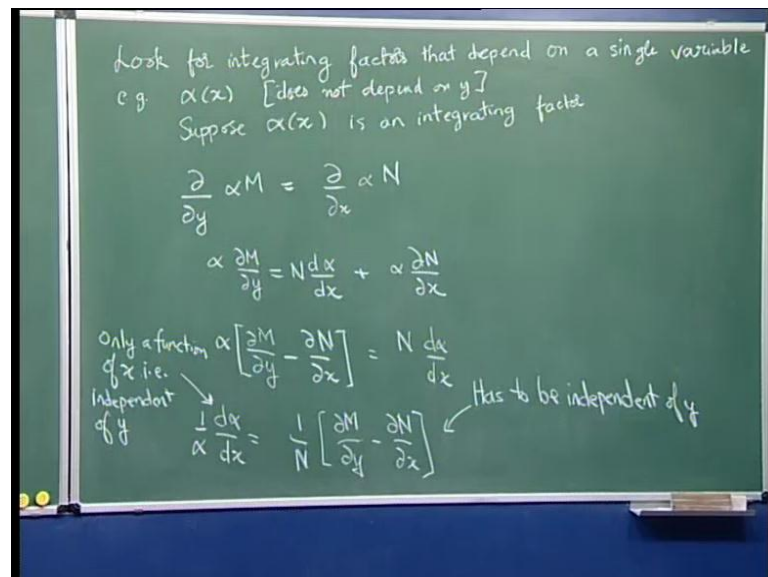

Now, the question is suppose you have a differential equation that is not exact, suppose this is not satisfied. So, if this is true then  $du = M dx + N dy$ , you can write in that form, I have omitted the dependence on  $x$  and  $y$ . So, it will be it is understood that  $M$  is a function of  $x$  and  $y$   $N$  as  $N$ , then  $du$  is an exact differential and the solution can be written as  $du = 0$  or  $u = \text{constant}$ . And we saw in the last class how you can solve for  $u$ .

Now, what happens suppose this is not an exact differential, so  $M(x,y) dx + N(x,y) dy$  is not exact, that is  $\frac{\partial M}{\partial y} \neq \frac{\partial N}{\partial x}$ . So, if you have this situation then there exist it is possible to show that there exist a variety of integrating factors  $\alpha$

which is, in general a function of  $x$   $y$ . So, there exist a large number of integration factors or there exists one or more integration factors such that  $\alpha M dx + \alpha N dy$  is exact, so I am just multiplying this, this original differential equation by  $\alpha$ .

So, I have the same differential equation, but then the you have  $\frac{d}{dy}$  of  $\alpha M$  is equal to  $\frac{d}{dx}$  of  $\alpha N$ , where  $\alpha$  is a function of  $x$  and  $y$ , so  $\alpha$  is a function of  $x$  and  $y$ . So, there exist these integration factors such that this is exact now, the question is how if this exists how would you go about to finding the  $\alpha$ . So, in general it is not easy to find  $\alpha$  because  $\alpha$  will satisfy a differential equation.

(Refer Slide Time: 04:28)

We assume or rather we look for integration factors that depend on a single variable. For example,  $\alpha$  of  $x$ , so we specifically look for such integrating factors not all and you may or may not find it. But suppose  $\alpha x$  is an integrating factor. Suppose  $\alpha x$  this is independent of  $y$ , so suppose  $\alpha x$  is an integrating factor. Then  $\frac{d}{dy}$  of  $\alpha M$  is equal to  $\frac{d}{dx}$  of  $\alpha N$ . Now,  $\alpha$  depends only on  $x$ , so this can be written as  $\alpha \frac{dM}{dy}$  by  $\frac{d}{dy}$  is equal to and in this case you will have both terms, so in this case since we are differentiating with respect to  $y$   $\alpha$  is independent of  $y$  it comes outside the differential.

So, I have  $\alpha$  times  $\frac{dM}{dy}$  by  $\frac{d}{dy}$  and now in this case partial derivative with respect to  $x$  of  $\alpha N$  will have two terms. First one will involve derivative with respect to  $x$  of  $\alpha$  and the second one will involve derivative with respect to  $x$  of  $N$ .

So, the first term will be  $d\alpha$  by  $dx$  into  $N + \alpha \frac{dN}{dx}$ . Notice this is an ordinary differential because  $\alpha$  depends only on  $x$  whereas, this is a partial derivative because  $n$  depends on both  $x$  and  $y$ .

And now I can rearrange this equation to write it as  $\alpha \frac{dM}{dy} - \frac{dN}{dx}$ . So, I bring this  $M$  this side is equal to  $N \frac{d\alpha}{dx}$  and this implies  $\alpha \frac{d\alpha}{dx} = \frac{1}{N} \frac{dN}{dx}$  that you write it slightly differently I will write it as  $\frac{1}{\alpha} \frac{d\alpha}{dx} = \frac{1}{N} \frac{dN}{dx}$ . Now, the left hand side depends only on  $x$ , so the left hand side is only a function of  $x$  independent of  $y$  i.e. independent of  $y$ .

So, since  $\alpha$  is only a function of  $x$   $\frac{d\alpha}{dx}$  will only be a function of  $x$  and  $\frac{1}{\alpha} \frac{d\alpha}{dx}$  will only be a function of  $x$ . So, the condition for  $\alpha$  to be an integration factor is that the right hand side should also be independent of  $y$ . So, the right hand side has to be independent of  $y$  and so the condition for that to exist an integration factor  $\alpha$  which depends only on  $x$  is that  $\frac{1}{N} \frac{dM}{dy} - \frac{dN}{dx}$  has to be independent of  $y$ .

So, if this condition has satisfied if this is only a function of  $x$  then you can calculate the integration factor by integrating out. So, the condition for there to exist an integration factor  $\alpha$  which is only a function of  $x$  is that  $\frac{1}{\alpha} \frac{d\alpha}{dx} = \frac{1}{N} \frac{dM}{dy} - \frac{dN}{dx}$  has to equal this right hand side. Or in other words  $\frac{1}{N} \frac{dM}{dy} - \frac{dN}{dx}$  has to be a function only of  $x$ .

(Refer Slide Time: 10:16)

$$\frac{dx}{x} = \frac{1}{N} \left[ \frac{\partial M}{\partial y} - \frac{\partial N}{\partial x} \right] dx$$
$$\ln \alpha = \int \frac{1}{N} \left( \frac{\partial M}{\partial y} - \frac{\partial N}{\partial x} \right) dx + C$$

Alternatively, look for integrating factor  $\beta(y)$

$$M \frac{d\beta}{dy} + \beta \frac{\partial M}{\partial y} = \beta \frac{\partial N}{\partial x}$$
$$\frac{1}{\beta} \frac{d\beta}{dy} = -\frac{1}{M} \left( \frac{\partial M}{\partial y} - \frac{\partial N}{\partial x} \right)$$

Now, if this is a function of  $x$  then we can integrate it out, so you can say  $d \alpha$  by  $\alpha$  is equal to  $\frac{dx}{x}$  and you can integrate this out. So, you will say natural log of  $\alpha$  is equal to integral plus a constant. So, you just integrate both sides and you have a constant of integration. So, the strategy is you calculate this quantity and you see if it is a function of  $x$ , if it is a function  $x$  then you are done you have your integration factor.

Now, another way to do this instead of looking for an integration factor that depends only on  $x$  we, will look for an integration factor. So, alternatively look for integrated factor  $\beta$ , which is only a function of  $y$ , it is independent of  $x$ . And you can go through the same arguments so you say that the instead of  $\alpha$  you will have  $\beta$  and you have the same condition but,  $\beta$  depends only on  $y$ . So, in this case it will come outside the integral.

And you can show that your condition will look like  $y$  into  $M$  plus  $\frac{dM}{dy}$  is equal to  $\beta \frac{dN}{dx}$ . And if you rearrange this you will get something like  $\frac{1}{\beta} \frac{d\beta}{dy} = -\frac{1}{M} \left( \frac{dM}{dy} - \frac{dN}{dx} \right)$  and now the left hand side depends only on  $y$ . So, the condition is that the right hand side should depend only on  $y$ , so this has to be independent of  $x$ . So, if this is independent of  $x$  if this right hand side is independent of  $x$  then you can find this integration factor  $\beta$  of  $y$  and you can calculate  $\beta$  in the same way by integrating out.

So, what we notice is that in both these conditions you have the same expression  $\frac{M}{N}$  by  $dy$  minus  $\frac{N}{M}$  by  $dx$ . In one case you divided by  $N$  and you should get a function that is independent of  $y$ , in the other case you divided by  $M$  to get a function that is independent of  $x$ . So, the usual strategy when we solve these differential equations is to first calculate this quantity see, if you divided by  $M$  or  $N$  do you get the appropriate function that is independent of one variable.

And if you get that and then you know that an integration factor exists. So, let us look at an example of applying this integration factor. So, let us take a specific example of a problem and see how we can calculate the integration factor.

(Refer Slide Time: 14:59)

So, the problem is  $2xy dx + 3x^2 dy = 0$  now the first thing you will say is that this can be solved by separation of variables. But let us go ahead and try to use the integration factor so what we will do is  $\frac{M}{N}$  by  $dy$  is  $dx$  by  $dx$  of this is equal to  $2x$ . So, you say that  $4x$  now if I divide this by so if I now look at  $\frac{1}{N}$  is equal to minus  $4x$  by  $3x^2$  is equal to minus  $\frac{4}{3x}$  and it is independent of  $y$ . So,  $\frac{1}{M} \left( \frac{\partial M}{\partial y} - \frac{\partial N}{\partial x} \right)$  is independent of  $y$ . So,  $\alpha(x)$  exists so we have an integration factor that depends only on  $x$  and you can calculate this integration factor.

(Refer Slide Time: 17:09)

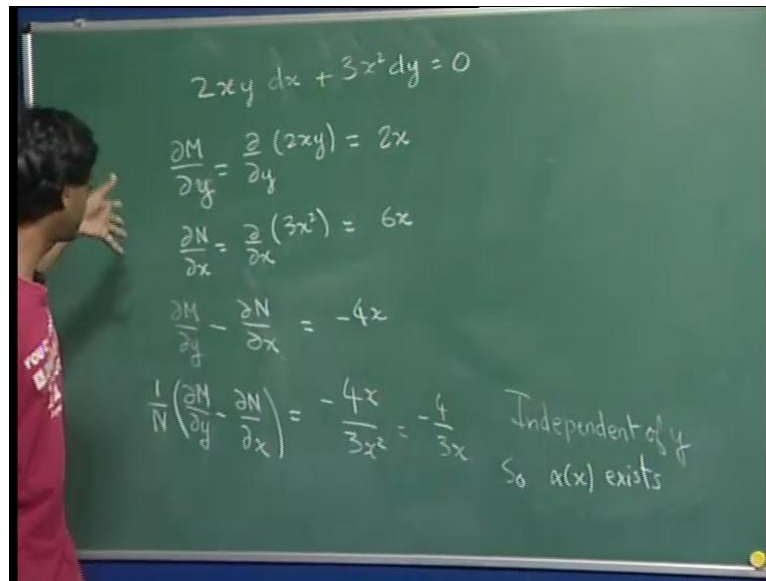

$$\ln \alpha = \int \frac{-4}{3x} dx + c$$
$$\ln \alpha = -\frac{4}{3} \ln x + c$$
$$= \ln x^{-4/3} + c$$
$$\alpha = e^{c x^{-4/3}}$$
$$= x^{-4/3}$$
$$2y x^{-1/3} dx + 3x^{2/3} dy = 0 \Rightarrow \text{Exact differential}$$
$$\text{Verify } \frac{\partial M}{\partial y} = 2x^{-1/3} = \frac{\partial N}{\partial x} = 3 \times \frac{2}{3} x^{-4/3} = 2x^{-4/3}$$

So, you say that  $\ln \alpha$  is equal to integral minus 4 by 3 x d x plus constant is equal to plus constant. And if you work this out you will get  $\ln$  of x to the power minus 4 by 3 plus constant, and you can write  $\alpha$  is equal to e raise to c 4 by 3. And this is just another constant e raise to c is just another constant so  $\alpha$  is equal to x to the power minus 4 by 3. So, the constant of integration we do not need to worry about this. So, we just choose this as your integrating factor.

Now, if I choose this as an integration factor then your differential equation becomes  $2y$ , now if you multiply this by x to the minus 4 by 3. So, will get x to the minus 1 by 3 d x plus 3 now you have x to the 2 by 3 d y equal to 0. So, I just multiplied this differential equation by x to the minus 4 by 3 and when you do this then you can calculate you can verify that 1 by 3 is equal to dou N by dou x, so you have 3 into 2 by 3. So, that is 3 into 2 by 3 x to minus 1 by 3 equal to 2 x to minus 1 by 3.

So, clearly  $2x$  to the minus 1 by 3 is equal to dou M by dou y and it is equal to dou N by dou x. So, this is an exact differential, and once you know that this an exact differential you can find your u by the methods that we discussed earlier.

(Refer Slide Time: 20:09)

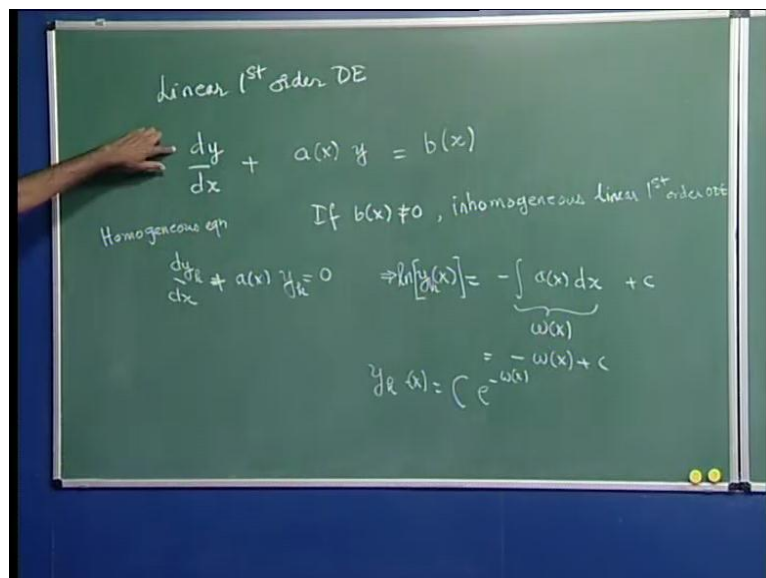

The chalkboard shows the following work:

$$2xy \, dx + 3x^2 \, dy = 0$$
$$\frac{\partial M}{\partial y} = \frac{\partial (2xy)}{\partial y} = 2x$$
$$\frac{\partial N}{\partial x} = \frac{\partial (3x^2)}{\partial x} = 6x$$
$$\frac{\partial M}{\partial y} - \frac{\partial N}{\partial x} = -4x$$
$$\frac{1}{N} \left( \frac{\partial M}{\partial y} - \frac{\partial N}{\partial x} \right) = \frac{-4x}{3x^2} = -\frac{4}{3x}$$

Independent of  $y$   
So  $\mu(x)$  exists

So, this is a procedure for finding the integration factor first you calculate  $\frac{\partial M}{\partial y}$  minus  $\frac{\partial N}{\partial x}$ . Then you look at your  $M$  and  $N$  and you see whether dividing by  $N$  you get a function only of  $x$  or dividing by  $M$  you get a function only of  $y$ . In this case actually we could have also found that integration factor that depends only on  $y$  because; if you divide this by  $M$  then you will get a function only of  $y$ . So, you can do it either way and you should get the same answer.

(Refer Slide Time: 20:46)

The chalkboard shows the following work:

Linear 1<sup>st</sup> order DE

$$\frac{dy}{dx} + a(x)y = b(x)$$

Homogeneous eq:  $\frac{dy}{dx} + a(x)y = 0$

If  $b(x) \neq 0$ , inhomogeneous linear 1<sup>st</sup> order ODE

$$\Rightarrow \ln[y_h(x)] = - \int a(x) \, dx + c$$
$$y_h(x) = e^{-w(x)}$$

where  $w(x) = \int a(x) \, dx$

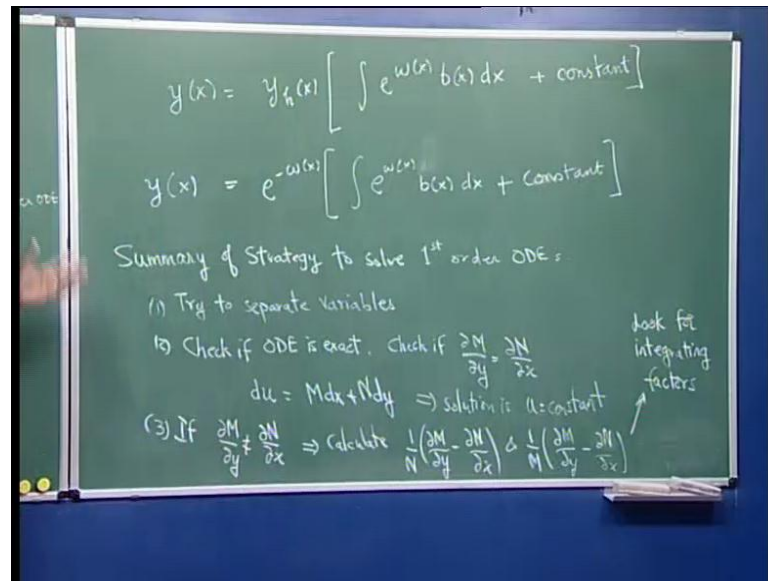

Now, we can look at a general linear first order differential equation. And this is of the form  $\frac{dy}{dx} + a(x)y = b(x)$ . So, it is linear because each term contains either  $y$  or it is derivative up to first power, and this is inhomogeneous. So, this is if  $b(x)$  is not equal to 0 then it is inhomogeneous linear 1, now the question is how will we solve this. So, in order to solve this we can use the methods of method of integration factors and we can and you can go through the details and work out the solutions.

In all in order to write the solution we will first look at the homogeneous equation. So, the homogeneous equation  $\frac{dy}{dx} + a(x)y = 0$ . So, this homogeneous equation can be solved by separation of variables you take so if I take this on the right that bring the  $y$  below. So, this is just integral minus  $a(x) dx$  plus constant. So, this is the solution of the homogenous equation and I will call this  $y_h$ .

So, the solution of the homogeneous equation is given by this oh sorry it should be  $e^{-\int a(x) dx}$  to the minus. So,  $\ln$  of  $y$  is equal to this. Now, let me call this quantity  $w(x)$  then this is minus plus some constant, in other words the homogeneous equation has a solution. So,  $e^{-\int a(x) dx} w(x) = C$  and on that  $e^{-\int a(x) dx}$  I will just write it as a constant capital  $C$ . So, this is the solution of the homogeneous differential equation so the homogeneous equation means you put  $b(x)$  equal to 0. Now, the inhomogeneous equation the solution of this differential equation is related to the solution of this homogeneous equation in this form.

(Refer Slide Time: 24:20)

Now, in a homogeneous equation the solution of this differential equation is related to the solution of this homogeneous equation in this form is equal to  $h$  of  $x$  times integral  $d$   $x$  plus constant. So, you can show by the method of integration factors. You look for an integration factor that depends only on  $x$  and you can show that the integration factor will give you this final solution. And so finally, you will get  $e$  to the minus  $w$   $x$  plus.

So, this is the general solution of an inhomogeneous linear first order differential equation. And I leave it as an exercise you to verify that this is indeed the solution and as I said you can do this by method of integration factors. So, that concludes the part of involving first order differential equations, I will just summarize the strategy, so order O D E s. So, the summary the strategy to solve first order differential equations is first thing is to try to separate variables.

If you are able to separate variables then you will separate it and you solve the differential equation. If you are not able to separate then the next strategy is to check if O D E is exact. So, you check if your ordinary differential equation is an exact differential in other words check if  $du$  by  $dx$ . So, if this is satisfied then you can find the solution as  $u$  is equal to  $du$  equal to  $M dx$  plus  $N dy$ , so we can write  $du$  equal to  $M dx$  plus  $N dy$  and solution is  $u$  equal to constant.

So, once you know that your ordinary differential is exact then you can solve this. And the third strategy if it is not exact, if by  $du$   $y$  not equal to  $du$   $x$ . Then the strategy is

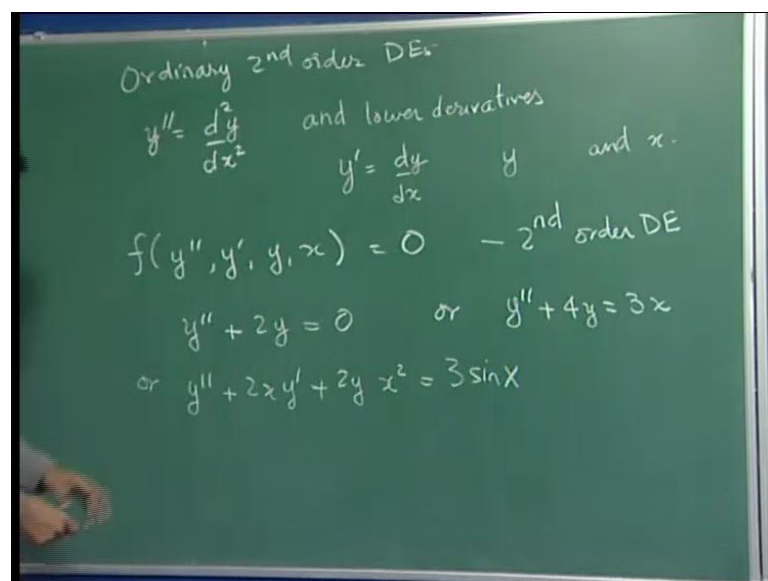

calculate  $\frac{1}{N}$  and so you calculate both these terms  $\frac{1}{M}$  to  $\frac{1}{N}$  times  $\frac{dy}{dx}$  by  $\frac{dy}{dx}$  minus  $\frac{dy}{dx}$  by  $\frac{dy}{dx}$  and  $\frac{1}{M}$  times  $\frac{dy}{dx}$  by  $\frac{dy}{dx}$  minus  $\frac{dy}{dx}$  by  $\frac{dy}{dx}$ . Then you check if this is only a function of  $x$  or you check if this will be a function of  $y$ , if this is only a function of  $x$  then you can find the integration factors.

If this is only a function of  $y$  you can find the integration factors. And then look for integrating factors. So, this is the general strategy for solving first order differential equations, and in case this is not independent of  $y$  and this is not independent of  $x$ . Then there exists no integration factors and you can not solve the differential equation using these procedures.

So, now we will start discussing second order differential equations and how you solve second order differential equations. So, it turns out that second order differential equations are the most commonly encountered type of differential equations in most applications. Some common ones that you have seen are the Schrodinger equation, and the diffusion equation and so on.

But, in general second order differential equations are some of the most commonly encountered differential equations. So, now what are the techniques that we use to solve second order differential equations, and for now we will restrict ourselves to ordinary second order differential equations, so ordinary D E.

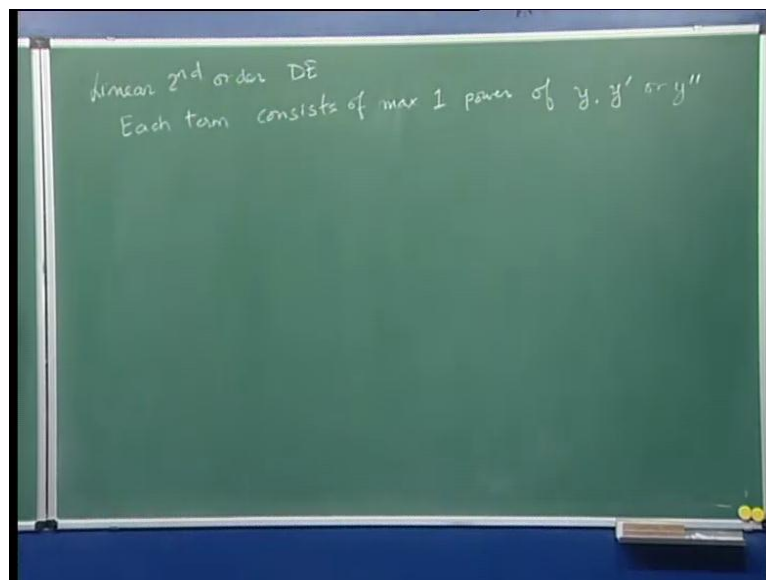

(Refer Slide Time: 31:01)

Now, second order differential equation is something that contains  $y$  double prime. So, second derivative of  $y$  square it contains  $y$  double prime, and it contains lower derivatives. So, the lower derivatives will be  $y$  prime and  $x$ .

So, it is an equation containing  $y$  double prime,  $y$  prime,  $y$  and  $x$ . So, you can write it as some function of  $y$  prime  $y$   $x$  equal to 0. So, this is our second order differential equations. For example, you can have  $y$  double prime plus 2  $y$  equal to 0, it is an example of a differential equation. So, it contains this particular equation contains only  $y$  double prime and  $y$ , but in general it can contain all those. So, or we can have 3  $x$  or you can have, so this contains  $y$  double prime,  $y$  prime,  $y$  and  $x$ . So, it can contain some or all of these and that is what forms a second order differential equation.

(Refer Slide Time: 33:18)

Now, let us look at some types of second order differential equation a linear order differential equation. So, a linear second order differential equation is one in which each term consists of only 1 power of  $y$  prime or  $y$  double prime or I should not say only 1. So, at most 1, so right way to say this of maximum 1 power of  $y$  prime or  $y$  double prime.

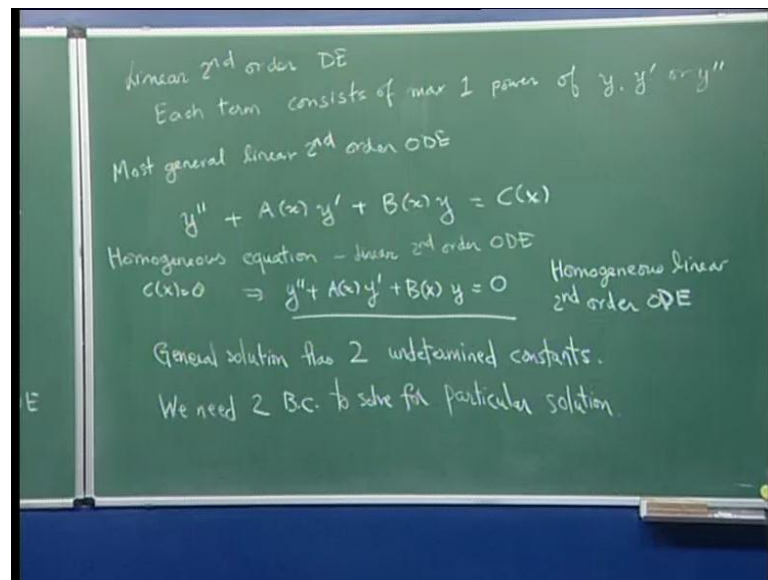

(Refer Slide Time: 34:10)

So, for example, if you look at these equations if you notice if you look at this equation the first term contains  $y$  double prime second term contains  $y$ . So, this is a linear second order differential equation. Similarly, you look at this contains  $y$  double prime this contains only 1  $y$  prime this contains  $y$ , this is also a linear second order differential equation. So, these are all linear similarly, this also contains each term contains only 1 power of  $y$ .

So, an example of on the other hand if you had something like  $y$  double prime plus  $y$  square equal to 0. Now, this contains  $y$  to the second power. So, this is a non-linear O D E similarly, you could have a non-linear second order O D E of the form. So, this term contains 1 power of  $y$  prime and 1 power of  $y$ , so effectively it contains two powers of  $y$  or it is derivatives. So, this is another non-linear, so you can have linear or non-linear second order differential equation.

(Refer Slide Time: 35:42)

So, the most general linear second order O D E. Now, what is the most general form of this linear second order differential equation that is you can write it as  $y$  double prime plus  $a$  of  $x$   $y$  prime plus  $b$  of  $x$   $y$  equal to  $c$  of  $x$ . So, this contains second derivative of  $y$ , this contains first derivative of  $y$  and some function of  $x$ , this contains  $y$  and some function of  $x$  and this contains a constant. So, this is the most general linear second order ordinary differential equation.

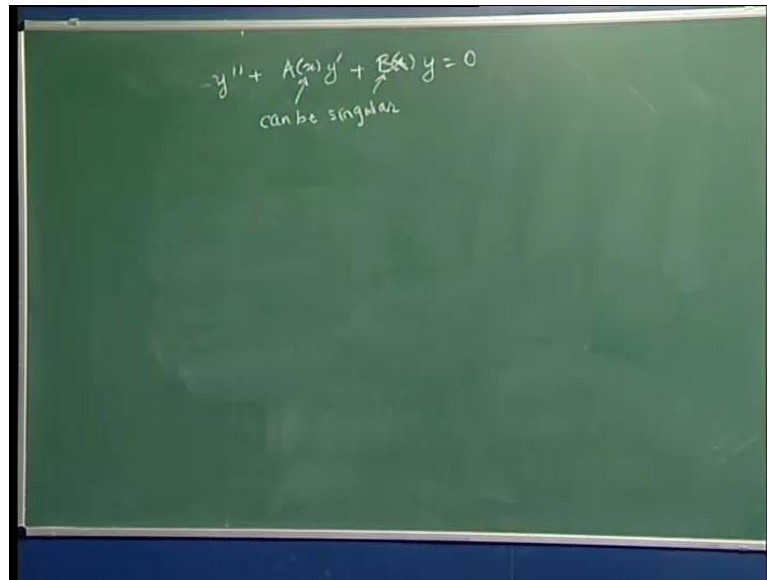

Now, we have already learn what are a homogeneous equation is one in which each term contains  $y$  to the same power of  $y$  or it is derivatives. So, homogeneous equation linear second order O D E. So, a homogeneous linear second order differential equation that is a special class of these where,  $c$  of  $x$  equal to 0. So, that implies this is homogeneous linear O D E. So, this is one class of linear second order differential equations is the homogenous one.

Now, there is something very interesting that happens with these homogeneous equations and that is what we will explore in the rest of today's class what I want to mention right the beginning is that if you have a second order differential equation, then the general solution it has 2 undetermined constants. So, in the general solution of a second order differential equations has two undetermined constants.

And so we need 2 boundary conditions in order to solve for the particular solution. So, this is a this is a brief summary of second order differential equations and what we will

do now is to look at various cases, we will look at methods to solve them, we will look at how a general solution can be constructed and so on. So, that will be the topic of the rest of this class, and the next few lectures. So, now let us look at the homogeneous equations.

(Refer Slide Time: 39:59)

$$y'' + A(x)y' + B(x)y = 0$$

can be singular

So, of the form  $y'' + A(x)y' + B(x)y = 0$ . Now, some of you might wonder why I did not put a some function of  $x$  here. And the answer is that you can take that function of  $x$  and you can include it in the  $A(x)$ .

So, suppose I had  $c(x)$  here, then I just divide the whole equation by  $c(x)$  and I take the factor of  $c(x)$  into the  $A(x)$ . So, in a sense  $A(x)$  can be singular, so it can go to infinity at some points and so on. Now, the question is  $A(x)$  and  $B(x)$  both of them can be divergent at some point. So, there might be certain values of  $x$  for which these functions go to infinity. So, now let us go to certain properties of the solutions now the property of the solutions that we are most interested in is the following.

(Refer Slide Time: 41:19)

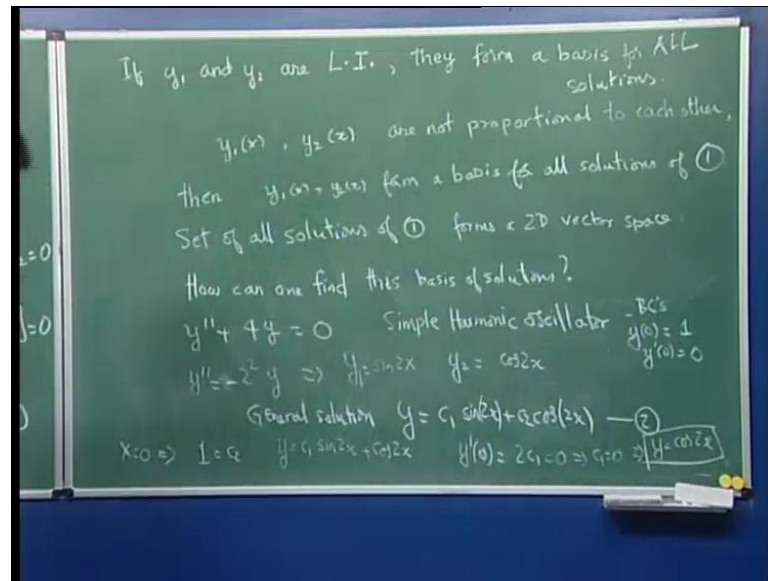

Suppose  $y_1$  and  $y_2$  are solutions of I will call this equation 1 of 1. So, suppose  $y_1$  and  $y_2$  are solutions of 1, then  $c_1 y_1 + c_2 y_2$  is also a solution of 1. So, where  $c_1, c_2$  are arbitrary constants, so suppose  $y_1$  and  $y_2$  are solutions of this equation and clearly a any linear combination of these two will also be a solution of this equation. It is very easy to prove you can just substitute in this equation, what I will get is  $c_1 y_1'' + c_2 y_2'' + A(x) c_1 y_1' + A(x) c_2 y_2' + B(x) c_1 y_1 + B(x) c_2 y_2 = 0$ .

And what you can see immediately is that you take the  $c_1$  terms we will get  $c_1 y_1'' + A(x) y_1 y_1' + c_2 y_2'' + A(x) y_2' = 0$ . So, what I did is I substituted in this equation and when I substitute this when I take the terms containing  $C_1$ , so I have first term is  $C_1 y_1''$  then I have a  $C_1 y_1' + A(x) C_1$  and I will get  $C_1 B(x) y_1$ , so  $B(x) y_1$  and similarly, with  $C_2$ .

Now, this is equal to 0 because  $y_1$  is a solution of this differential equation, and. So, this whole thing is equal to 0. And that implies  $C_1 y_1 + C_2 y_2$  is the solution of one. So, this is the a very important property that says, that if you have two solutions of the differential equation any linear combination of them is also a solution to this second order homogeneous differential equation.

(Refer Slide Time: 44:56)

Now, the next question is or the next comment is that is in if  $y_1$  and  $y_2$  are linearly independent they form a basis for all solutions and I should say this with a little bit of caution, because there might be some solutions that might not be expressible in this form. So, the statement is that if  $y_1$  and  $y_2$  are linearly independent. So,  $y_1$  is a function of  $x$ ,  $y_2$  is a function of  $x$ . So, if these two are linearly independent and when I say that they are linearly independent; that means, they are not proportional to each other.

Then  $y_1$  of  $x$ ,  $y_2$  of  $x$  form a basis for all solutions, so if they are not proportional to each other they form a basis for all solutions of 1. So, the point is you have this differential equation. So, if you know two linearly independent solutions then any solution can be expressed as a linear combination of these solutions, so that is the idea. So, in a sense if you have a vector space you say that any vector can be written as a linear combination of the basis vectors.

So, same way if you have the set of solutions any solution can be expressed as a linear combination of these two solutions. Now, incidentally you also notice that  $y$  equal to 0 is a trivial solution of this equation. So,  $y$  equal to 0 satisfies this equation in a very trivial way. So, actually you can show that the set of solutions forms a vector space, this satisfies the axioms of a vector space. So, you can set of all solutions of 1 forms a 2 D vector space.

So, it forms a 2 D vector space because if  $y_1$  and  $y_2$  are solutions then any linear combination of them is also a solution. So, this is a very useful property, so the question. So, the biggest question is how do we find the basis. So, how one find this basis of solutions so just to reiterate what we want to do is to find two linearly independent solutions. Two solutions to this differential equation which are not proportional to each other, so now, the question is how do you find this basis and that is the challenge of these second order differential equations.

And we will look at various strategies for finding this solution of these differential equations. So, let us take a very simple example and we will and see how this works we will take an example where they are familiar with the solutions. And then later on we will go to more complicated cases, so let us take the example  $y'' + 4y = 0$ . And you will immediately tell me that this equation is of the form of a simple harmonic oscillator.

So, this is a simple harmonic oscillator and the solution is of the form. So, this is  $y'' + 2^2 y = 0$  or  $y'' = -2^2 y$  implies  $y = y_1 \sin 2x + y_2 \cos 2x$ . So,  $y_1$  is  $\sin 2x$   $y_2$  is  $\cos 2x$  and these 2 are these 2 are linearly independent and so they form a basis. So, the general solution  $y = C_1 \sin 2x + C_2 \cos 2x$ .

So, the general solution to this differential equation can be written in this form and depending on the boundary conditions you can put the boundary conditions and you can solve for  $C_1$  and  $C_2$ . So, suppose I give the boundary conditions, so suppose I say boundary conditions  $y(0) = 1$   $y'(0) = 0$ . So, these are my 2 boundaries suppose I had these two as my boundary conditions then what you will do is  $y(0)$  is if I substitute if I put  $x = 0$  in this.

So, I will call this 2 so put  $x = 0$  in 2. So,  $x = 0$  implies the  $\sin 2x$  term will go away we will have  $\cos 2x = 1$   $\cos 2 \cdot 0$  that is 1. So, you will have  $C_2 = 1$ . So,  $1 = C_2$ , so you have determined  $C_2$  and if you do that then you have  $y = C_1 \sin 2x + \cos 2x$ . So, then you take the derivative, so  $y'$  is equal to or  $y'$  at 0 is equal to. So, if I take the derivative here I will get  $2C_1 \cos 2x$  and if I put  $x = 0$   $\cos 2x = \cos 0$  which is 1. So, I have  $2C_1$  in this case derivative is  $2 \sin 2x$ .

When  $x$  equal to 0 that derivative goes to 0. So,  $2 C_1$  equal to 0 implies  $C_1$  equal to 0, so we have determines. So, the  $C_2$  is  $1$   $C_1$  is 0. So, the particular solution  $y$  is equal to  $\cos 2x$  implies  $y$  equal to  $\cos 2x$ . So, this is the particular solution with no undetermined constants. So, what we had is we had a differential equation  $y'' + 4y = 0$  and the solution was written as  $y$  is equal to  $C_1 \sin 2x$  plus  $C_2 \cos 2x$ .

(Refer Slide Time: 52:48)

That was a general solution and we said that the basis vectors are  $\sin 2x$  and  $\cos 2x$  form a basis. Now, the next thing is let us try to do it in a slightly different way now, instead of saying  $\sin 2x$  and  $\cos 2x$  suppose I could have said  $y_1$  is equal to  $e^{i2x}$  and  $y_2$  is equal to  $e^{-i2x}$ . So, what all I said this is also a solution to this differential equation. And I could have used this as a solution, so this also forms a basis and you can see that. So, that implies that our original basis is not a unique basis they can be other basis also.

And that should be fairly obvious because you can write  $e^{i2x}$  is equal to  $\cos 2x$  plus  $i \sin 2x$ , and so we wrote  $y_1$  as a linear combination of these 2 basis. So, this implies that you can go from one basis to the other and so if  $\cos 2x$  and  $\sin 2x$  are a basis also  $e^{i2x}$  and  $e^{-i2x}$  also form a basis. So, you should not be surprised if you get very different looking forms of basis, because indeed the basis are not unique.
