Lecture - 38
Introduction to Consolidation and Dynamic Analysis

Hello students, good morning. I hope you are doing well in the course and you remember what we did in the previous classes. We were looking at the different ways of correcting the stresses and then we had seen different methods of non-linear analysis using initial stress and then the tangent stiffness method and so on. And some examples of the bearing capacity calculations were seen in the previous class. And today's class let us look at the elastic plastic modelling of the soils.

(Refer Slide Time: 01:03)

The slide is titled "Outline" and contains a bulleted list of topics. To the right of the list is a vertical banner with the NPTEL logo, the course title "FEA & CM", the instructor's name "Dr. K. Rajagopal", and a small video thumbnail of the instructor. The slide footer includes "FEA&CM Lecture-32" and the number "2".

Outline

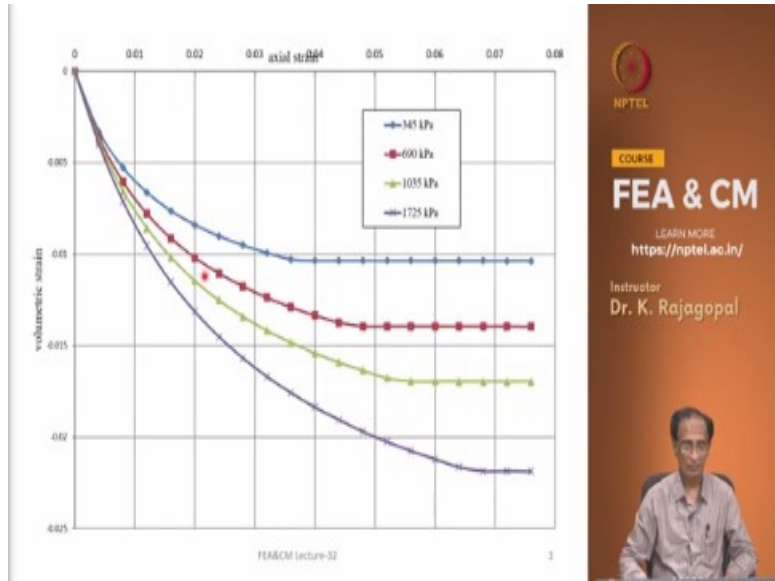

- Linear & nonlinear elastic constitutive models could not simulate dilation
- Dilation – shear induced volume expansion
- Plasticity based constitutive models
- Some application of plasticity models

FEA&CM Lecture-32 2

Because till date although we had looked at number of different constituted models all of them were good and some of them were stress dependent that they can simulate the influence of both the stiffness and the strength and the confining pressure. But then they were not able to simulate the shear induced dilation or the volume expansion and at that time itself we had seen that all the elastic volumetric changes will be only compressive.

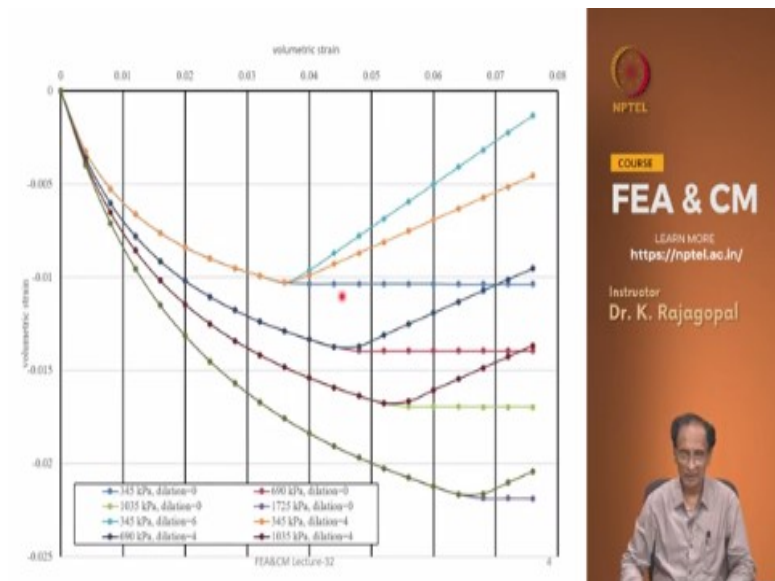

If your axial strain is compressive the volumetric strain within the triaxial compression test will also be compressive. And now we are going to look at a new approach to the modelling by introducing the plastic strains and this will give us a more capability of simulating the volume expansion and then the strength increase under suppressed dilatancy and so on.

(Refer Slide Time: 02:14)

See this is what we had seen these are the volumetric strains during the triaxial compression test and the x axis we have the axial strain on the y axis we have the volumetric strains a different confining pressures. And all of them were only compressive at all the different confining pressures.

(Refer Slide Time: 02:42)

And then this is what we want to simulate there might be initial compression and then after the soil reaches the plastic limit state there should be volume increase this is what we want to predict and in fact these are showing a different confining pressures and different dilation angles. This particular one is for a dilation angle of 0 and then this is for 4 degrees. I think this must be I did not market here this is for six degrees a dilation angle at a confining pressure of 345.

And we see that at a higher confining pressure the soil undergoes the volumetric compression for a longer axial strain. So, for example at confining pressure of 345 after axial strain of about a 0.035 the soil started expanding or it has reached a constant volume state but at this higher confining pressure of 1725 the plasticity has set in only at a axial strain of more than 0.06. And you notice that the slope of these lines is the same for the same dilation angle.

And although the confining pressure is different, we get the same slope that means that this particular model that we are going to discuss is still not realistic but then we can say that we are able to simulate volume expansion and so we should be happy.

(Refer Slide Time: 04:44)

Determination of dilation angle

From volume strains measured in CD triaxial compression tests,

$$\frac{d\varepsilon_v}{d\varepsilon_a} = \frac{-2 \sin \psi}{1 - \sin \psi}$$

For $\psi=15^\circ$, $d\varepsilon_a=7.5 \times 10^{-3}$, $d\varepsilon_v = -5.238 \times 10^{-3}$
 from finite element analysis (dilatant volume changes are taken as negative)

$d\varepsilon_a$ is the incremental axial strain and $d\varepsilon_v$ is the corresponding incremental volume strain

From direct shear & simple shear test data,

$$\tan \psi = \frac{-dy}{d\gamma}$$

For $\psi=15^\circ$, $d\gamma = 2 \times 10^{-3}$ & $dy = -5.35 \times 10^{-4}$

dy is the incremental vertical deformation and $d\gamma$ is the incremental shear strain

Instructor
 Dr. K. Rajagopal

So, how do we determine the dilation angle? So, previously we had seen how to determine the and the friction angle by either drawing a common tangent to all the more circles or within the pq space we can do a best fit line and then determine the cohesion and then the friction angle. And

the dilation angle we can determine from a consolidated drain test because we can measure the volume changes.

From volume strains measured in CD triaxial compression tests,

$$\frac{d\varepsilon_v}{d\varepsilon_a} = \frac{-2 \sin \psi}{1 - \sin \psi} \quad \text{For } \psi=15^\circ, d\varepsilon_a=7.5 \times 10^{-3}, d\varepsilon_v = -5.238 \times 10^{-3}$$

from finite element analysis (dilatant volume changes are taken as negative)

$d\varepsilon_a$ is the incremental axial strain and $d\varepsilon_v$ is the corresponding incremental volume strain

From direct shear & simple shear test data,

$$\tan \psi = \frac{-dy}{d\gamma} \quad \text{For } \psi=15^\circ, d\gamma = 2 \times 10^{-3} \text{ \& } dy = -5.35 \times 10^{-4}$$

And these are some of the theoretical relations for triaxial compression test the ratio between the incremental volume change to the incremental axial strain is in terms of the psi its - 2 times sin psi by 1 - sin psi is actually this is from the we can easily derive it based on our fundamental definition for d epsilon v, that is the volumetric strain. And these are the typical results these are from and the finite element program for a dilation angle of 15 degrees and the d epsilon a is 7.5 times 10 to the power of - 3.

And the corresponding d epsilon v is - 5.238 times 10 to the power of - 3 and if you substitute this and solve this equation and this, I will come to approximately 15 degrees. So, that is how we can actually determine the dilation angle. So, within the from the triaxial compression test we get the increment of volumetric strain and increment of axial strain. And then by using this equation we can back predict the dilation angle.

And similarly, from the direct shear and the simple shear test as we are applying shear strain, we are going to measure the vertical deformations and tan psi is - dy by d gamma is actually in all these cases the minus sign is to say that the expansion is negative. In the geotechnical sign convention, the tensile stresses are taken as negative and for this particular case for a friction angle sorry for a dilation angle of 15 degrees d gamma is this and dy is this much.

And so, if you substitute this back and take psi of psi as a tan inverse of this quantity, we will get approximately 15 degrees.

(Refer Slide Time: 07:53)

Influence of soil dilation on strength of soil in direct shear & simple shear tests

$$\frac{\tau_{\max}}{\sigma_n} = \frac{\sin \phi \cos \psi}{1 - \sin \phi \sin \psi}$$

$\tan 30 = 0.577$ & $\sin 30 = 0.50$

$$\psi = \phi \Rightarrow \frac{\tau_{\max}}{\sigma_n} = \tan \phi$$

$\tan 35 = 0.70$ & $\sin 35 = 0.574$

$$\psi = 0 \Rightarrow \frac{\tau_{\max}}{\sigma_n} = \sin \phi$$

This effect is seen in direct shear & simple shear tests and not seen in triaxial compression tests, why??

FEA&CM Lecture-32

And what is the influence of a dilation angle and the strength of the soil? And this we can derive this is a theoretical equation and there is a long derivation based on the more circle analysis. So, this I will give the proof as an MS Word file because it is a very long one and its quite boring to explain but then it is quite easy if you do it yourself. The tau max by sigma n is sin phi times cosine psi by 1 - sin phi sin psi and so if you substitute there is psi of equal to phi this quantity becomes tan phi.

Influence of soil dilation on strength of soil in direct shear & simple shear tests

$$\frac{\tau_{\max}}{\sigma_n} = \frac{\sin \phi \cos \psi}{1 - \sin \phi \sin \psi}$$

$\tan 30 = 0.577$ & $\sin 30 = 0.50$

$$\psi = \phi \Rightarrow \frac{\tau_{\max}}{\sigma_n} = \tan \phi$$

$\tan 35 = 0.70$ & $\sin 35 = 0.574$

$$\psi = 0 \Rightarrow \frac{\tau_{\max}}{\sigma_n} = \sin \phi$$

Because in the numerator we have sin phi times cosine phi by 1 - sin phi times sin phi that is 1 - sin square phi that is cosine square phi. So, end up with sin phi by cosine phi that is tan phi and if

dilation angle is 0 this τ_{max} by σ_n is a $\sin \phi$ and for any friction angle ϕ the $\tan \phi$ is more than $\sin \phi$. For example, for 30 degree $\tan 30$ is 0.577 and $\sin 30$ is 0.5 and for 35 degree $\tan 35$ is 0.7 and $\sin 35$ is 0.574.

And we see that as the dilation angle is increasing from 0 towards the friction angle, we will see some increase in the strength. And this effect we can see only in the direct shear and the simple shear test but not in triaxial compression test. Why? Because in the triaxial compression test the sample is free to expand in one direction so, we will not see the effect of the suppressed dilatancy in the triaxial compression test.

Whereas in the direct shear and simple shear we are doing the test in a rigid box and because of the rigid confinement the soil has to expand only in one direction and against and that expansion is happening against the applied pressure. So, because of that we will see some increase and it is easy to demonstrate through finite element analysis and that I will show you now.

(Refer Slide Time: 10:50)

Say here this is the plot between the axial strain and the deviate stress for three different dilation angles dilation angle of 0, 10 and 15. For all of them you get the same stress strain response because the soil is free to expand in the other direction without doing any extra work.

(Refer Slide Time: 11:18)

Whereas the stress strain response is the same but if you look at the volumetric strain response you get three different responses this is for a dilation angle of 0 this is for 10 degrees and this is for 15 degrees. And from the slope of these lines, we can back predict the dilation angle through the equation that I gave you earlier.

(Refer Slide Time: 11:46)

Whereas if we look at the simple shear test say the simple shear test is there are different varieties one is in a cubical box and that is one type of test and then there are other tests where we use cylindrical samples. But this is actually demonstrating only the and the cubicle sample test and there are some constraints within the simple shear test the epsilon xx is 0 that is the horizontal strain is 0.

So, that means that because basically we have a rigid box and that is both the vertical surfaces are moving by the same amount. That means that the relative displacement is 0 and so our epsilon xx is 0 and similarly in the y direction epsilon yy is constant and then the tau xy and the gamma xy is constant all through because the shear strain is constant. And we can since the stress state is constant, we can just use one single element for doing this simple shear test.

And this particular one that you are seeing this shows the deformed shape during the elastic state and you see that there is no volume change. Because it is basically it is a pure shear strain and under pure shear strain you will only get shear stresses and you will not get any volumetric strains either epsilon xx is anywhere 0 epsilon yy is 0 because we are not applying any strain or stress in the y direction. And so, you see that these two surfaces at the top they are exactly coinciding during the elastic state.

(Refer Slide Time: 13:59)

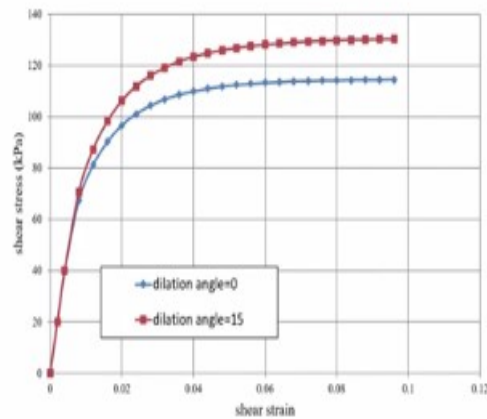

FEA&CM Lecture-32

10

Whereas if you look at the during the plastic state there is some volume expansion, say this the top line has moved up. This is for a dilation angle of 15 degrees and for a friction angle of 35 degrees.

(Refer Slide Time: 14:20)

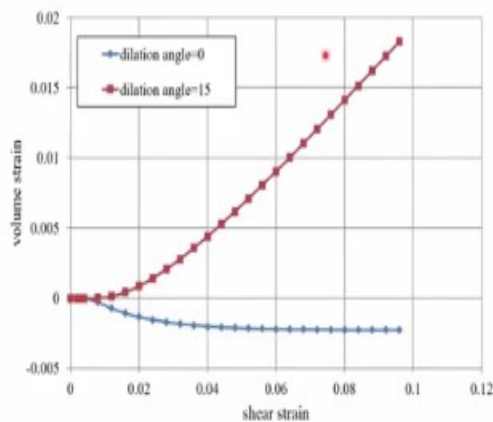

Simple shear test with different dilation angles, $c=0$, $\phi=35^\circ$

And you see two responses for a dilation angle of 0 this is the blue line and for the red for a dilation angle of 15 degrees you see an increased strength both for the same friction angle of 35 degrees and c of 0. So, you see the effect of dilation the soil wants to expand and this expansion is happening against the applied normal pressure, so because of that the soil has to do some additional work to induce this volume expansion or dilation. And that will result in a higher strength or higher stresses.

(Refer Slide Time: 15:07)

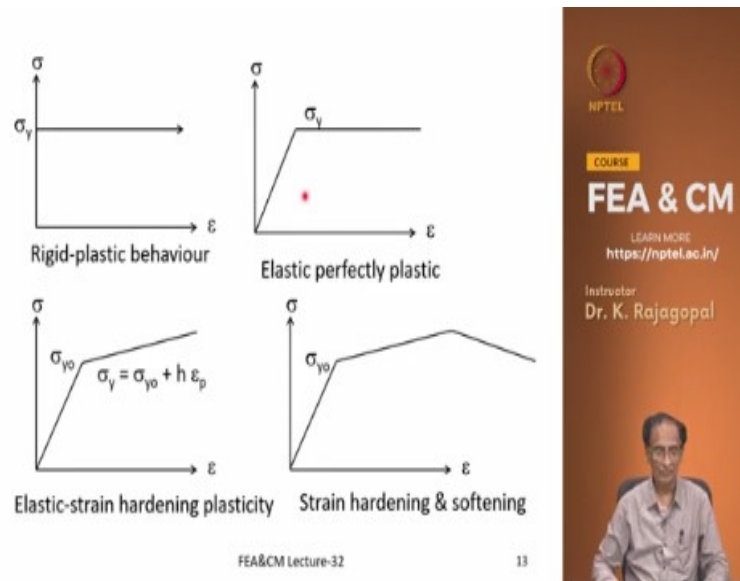

Simple shear test with different dilation angles

These are the volume strain responses, initially there is both of them have shown zero volume strain during the elastic state and then there is some compression with the dilation angle of 0 and then with the dilation angle of 15 degrees there is expansion.

(Refer Slide Time: 15:33)

And what are the different types of plasticity that we can model? One is the rigid plastic behaviour this is typical of the brittle materials. There is no elastic strain, elastic strain is 0 during the stress application soil does not the material does not undergo any strains. And suddenly it will reach a plastic state when you might end up with the infinite strain at the same stress of σ_y . σ_y is deal stress and then there is an elastic perfectly plastic.

Actually, in both of these models you see that the σ_y deal stress is remaining constant and that we call as perfect plasticity that is even with the plastic strains induced in the soil the strength is remaining constant. And this particular one is called as the elastic perfectly plastic, initially there are some elastic strains and then after the plastic limit is reached the stress remains constant and then we can have elastic strain hardening beyond an initial yield stress of σ_{y0} .

The stress will go on increasing because there is a hardening or there is a stiffening of the soil because of the plastic strain induced hardening and we can also have a strain softening. Say this particular behaviour is a typical of our loose sands where the soil will undergo compression and then the deviate stress will go on increasing until reaching some asymptotic limit. And we can also have a strain softening initially its elastic and then strain hardening the yield stress will go on increasing.

And beyond a point the yield stress will go on reducing or the stress reduces and this particular behaviour is similar to our dense sands there is a nice peak and then beyond the peak the stress will go on reducing and that we call as the strain softening, this is the strain hardening part and then the strain softening part. And there are different ways of modelling this and one simple model is we assume that the increase in the deal stress is proportional to the plastic strains.

Because normally in a continuum there are different varieties of plastic strains in x direction y direction and z direction and then then in the xy, yz and so on like we take a measure. And that I think I am not going to explain in this course, that is too advanced but there are different varieties of hardening rules. But in this case, in this course we are going to look at only the perfect plasticity perfectly elastic plastic materials where the yield stress remains constant.

(Refer Slide Time: 19:05)

Strain increment

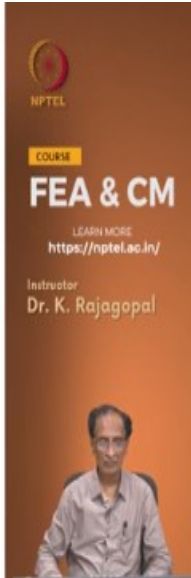

Elastic stress & strain relations

$$\{d\sigma_e\} = [D_e] \{d\varepsilon_e\}$$

$$\{d\varepsilon_e\} = [D_e]^{-1} \{d\sigma_e\}$$

$[D_e]$ is the elastic constitutive matrix formulated in terms of (E,ν) or (E,K) or (K, G), etc.

Elastic strains occur during the elastic phase of loading (i.e. when $F < 0$)

NPTEL
COURSE

FEA&CM Lecture-32
14

And let us look at how we can do this analysis. During the elastic state our stress and strain are related like this $d\sigma$ is D elastic times $d\varepsilon$ elastic D is the elastic constitutive matrix and we can write $d\varepsilon$ as d inverse of $d\sigma$ and D_e is the elastic constituted matrix formulated either in terms of Young's modulus poissons ratio or bulk modulus and the shear modulus are the Young's modulus and bulk modulus and so on that we have seen earlier.

Strain increment

Elastic stress & strain relations

$$\{d\sigma_e\} = [D_e] \{d\varepsilon_e\}$$

$$\{d\varepsilon_e\} = [D_e]^{-1} \{d\sigma_e\}$$

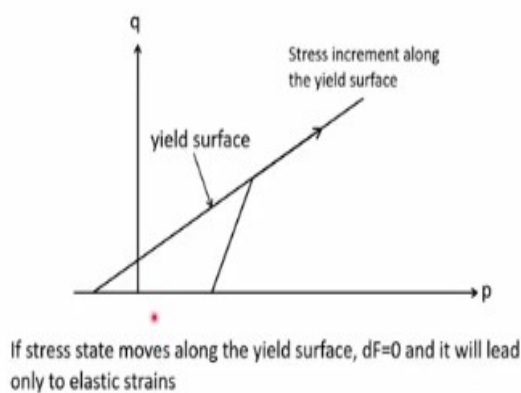

$[D_e]$ is the elastic constitutive matrix formulated in terms of (E, ν) or (E, K) or (K, G) , etc.

Elastic strains occur during the elastic phase of loading (i.e. when $F < 0$)

And the elastic strains occur during the elastic phase of the loading that is when the yield function is 0 is less than 0. The deal function we have seen earlier that enables us to examine whether the given stress state is in the elastic state or the plastic state that is when F is less than 0 the soil is in the elastic state and when it is 0 it is in the plastic state or we can also draw a more circle. If your more circle is below the yield surface, we say that particular stress state is elastic.

(Refer Slide Time: 20:31)

Stress increment along yield surface

FEA&CM Lecture-32

15

In the pq space our real surface a molecular meal surface is something like this and so if you plot any stress path initially our we have only normal stresses and the shear stress is 0, q is 0 and then the stress might increase then after reaching here the stress should move along the yield surface without exceeding the yield surface and this is the stress increment during the yield surface along the yield surface.

Stress increment along yield surface

And because this surface is actually our yield surface F and we can say that F remains constant along the surface or dF is 0.

(Refer Slide Time: 21:30)

Arbitrary stress increment

Any arbitrary stress increment can be resolved into a normal component and a tangential component

FEA&CM Lecture-32 16

COURSE

FEA & CM

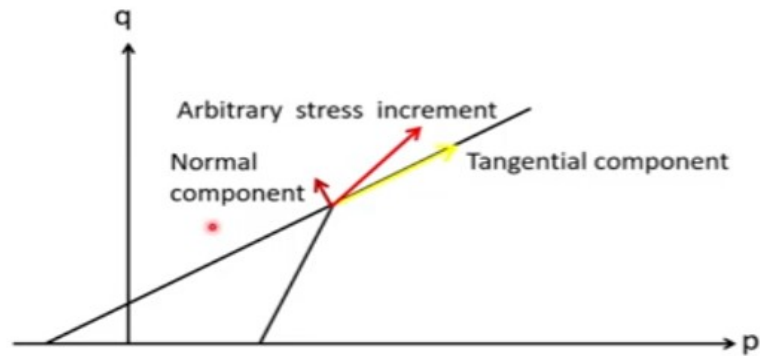

LEARN MORE
<https://nptel.ac.in/>

Instructor
Dr. K. Rajagopal

See we can apply any stress increment in any arbitrary stress increment like this say like this orange colour vector and we can resolve this into two components one is along the yield surface and the other is normal to the yield surface. And there is a tangential component then normal component and if our stresses are moving along the yield surface our yield function value remains constant and we will not be able to produce any plastic strains.

Arbitrary stress increment

Any arbitrary stress increment can be resolved into a normal component and a tangential component

All these strains that happen when your F is less than or equal to 0 or elastic and only the normal component is going to produce our plastic strains because it is trying to cause some strain and so this normal component can be represented as the derivative of this yield function F with respect to different stress component σ_x , σ_y , τ_{xy} and so on.

(Refer Slide Time: 22:59)

Normality rule

Only the normal component to the yield surface will produce plastic strains. Plastic strain increments are estimated as,

$$d\epsilon_p = d\lambda \frac{\partial F}{\partial \sigma}$$

$d\lambda$ is called as proportionality factor

- The same yield function F is used to check for the plastic limit state and also to estimate the plastic strain increments – called as Associated Plasticity.
- This was assumed in the original plasticity theories by Prandtl, Reuss, etc.

And the conventional plasticity or in the classical plasticity theories this rule is called as the normality rule the $d\epsilon_p$ is $d\lambda$ times $\frac{\partial F}{\partial \sigma}$ where $\frac{\partial F}{\partial \sigma}$ represents the normal yield surface and the p - q diagram p is the normal stress and the q is the

shear stress. In this diagram the yield surface is this very simple and dF by $d\sigma$ is your normal direction and the $d\lambda$ is actually it is a proportionality constant.

$$d\varepsilon_p = d\lambda \frac{\partial F}{\partial \sigma}$$

$d\lambda$ is called as proportionality factor

And that we need to determine we do not know it but we can determine the $d\lambda$ later. So, if you know $d\lambda$ and if you are able to evaluate dF by $d\sigma$ the plastic strain increments can be evaluated. And this type of plastic theory is called as the associated plasticity because we are using the same yield function F for checking for the yield and also for calculating the plastic strains.

So, our ref is defining this surface and we are also calculating the plastic strains as $d\lambda$ times dF by $d\sigma$ and this was assumed in the original plasticity theory developed by Prandtl and Reuss and others.

(Refer Slide Time: 24:46)

Non-associated plasticity rule

- When the associated plasticity was applied to soils, the predicted volume dilation was found to be much higher compared to measured values.
- Hence, an additional potential function Q was introduced in terms of dilation angle ψ which is lesser than friction angle ϕ .
- Now, the plastic strain increments are evaluated using the plastic potential function Q as,

$$d\varepsilon_p = d\lambda \frac{\partial Q}{\partial \sigma}$$

- As different functions are used to check for plasticity and estimation of plastic strains, this theory is called as non-associated plasticity rule.

FEA&CM Lecture-32 18

COURSE

FEA & CM

LEARN MORE
<https://nptel.ac.in/>

Instructor
Dr. K. Rajagopal

And when Terzaghi started applying those plasticity rules for the soils. See the metals do not have any friction angle because their strength is so much and their particles are so bounded together that any application of confining pressure will not change their shear strength, say for example you take the cubical samples sorry the cylindrical samples of metal like steel or some other material and then perform tetraaxial compression tests at three different confining pressures.

We will see that the strength does not change its immaterial in it is independent of the confining pressure so we will get a horizontal line in the pq diagram. And so that means that your friction angle is 0. But then for soils we see that the friction angle could be significant depending on the sand content. And when the associated plasticity rule was applied to soils the predicted volume dilation was very high.

Now, the plastic strain increments are evaluated using the plastic potential function Q as,

$$d\varepsilon_p = d\lambda \frac{\partial Q}{\partial \sigma}$$

And Terzaghi and others worked on a slightly different concept and they introduced an additional potential function Q, that is defined in terms of dilation angle psi and usually it is less than the friction angle phi. And the now the plastic strains d epsilon p are written as d lambda times dou Q by dou sigma, where Q is our potential function that is defined in terms of dilation angle psi and since we are using two different functions.

One function for evaluating the yield, yield condition that is defining the yield surface and another surface Q for determining the plastic strains. This theory is called as the non-associated the plasticity rule and this is more applicable for soil mechanics problems where the dilation is assumed to be lesser than what we get with the associated plasticity rules.

(Refer Slide Time: 27:18)

$$F = (\sigma_1 - \sigma_3) - (\sigma_1 + \sigma_3) \sin\phi - 2.c.\cos\phi$$

$$Q = (\sigma_1 - \sigma_3) - (\sigma_1 + \sigma_3) \sin\psi - 2.c.\cos\psi$$

When $\phi=\psi$; $F\equiv Q$, we get back associated plasticity

$$d\varepsilon_{1p} = d\lambda \frac{\partial Q}{\partial \sigma_1} = d\lambda.(1 - \sin\psi)$$

$$d\varepsilon_{2p} = 0$$

$$d\varepsilon_{3p} = d\lambda \frac{\partial Q}{\partial \sigma_3} = d\lambda.(-1 - \sin\psi)$$

$$d\varepsilon_{vp} = d\varepsilon_{1p} + d\varepsilon_{2p} + d\varepsilon_{3p} = -2.d\lambda.\sin\psi$$

- When $\psi>0$, the above equations shows negative volume strains (dilation) - hence plastic volume strains are expansive
- When $\psi=0^\circ$, plastic volumetric strains will be zero

FEA&CM Lecture-32

19

Say for example our yield function F was written in terms of sigma 1 and sigma 3 and c and phi like this and the same form of the function we can use for defining the Q but replace the friction angle phi with the dilation angle psi and when phi is psi their F and Q are the same and we get back our associated plasticity rule. And we can evaluate the plastic strains in different directions d epsilon 1p is a d lambda times dou Q by dou sigma 1.

$$F = (\sigma_1 - \sigma_3) - (\sigma_1 + \sigma_3) \sin\phi - 2.c.\cos\phi$$

$$Q = (\sigma_1 - \sigma_3) - (\sigma_1 + \sigma_3) \sin\psi - 2.c.\cos\psi$$

When $\phi=\psi$; $F\equiv Q$, we get back associated plasticity

$$d\varepsilon_{1p} = d\lambda \frac{\partial Q}{\partial \sigma_1} = d\lambda.(1 - \sin\psi)$$

$$d\varepsilon_{2p} = 0$$

$$d\varepsilon_{3p} = d\lambda \frac{\partial Q}{\partial \sigma_3} = d\lambda.(-1 - \sin\psi)$$

$$d\varepsilon_{vp} = d\varepsilon_{1p} + d\varepsilon_{2p} + d\varepsilon_{3p} = -2.d\lambda.\sin\psi$$

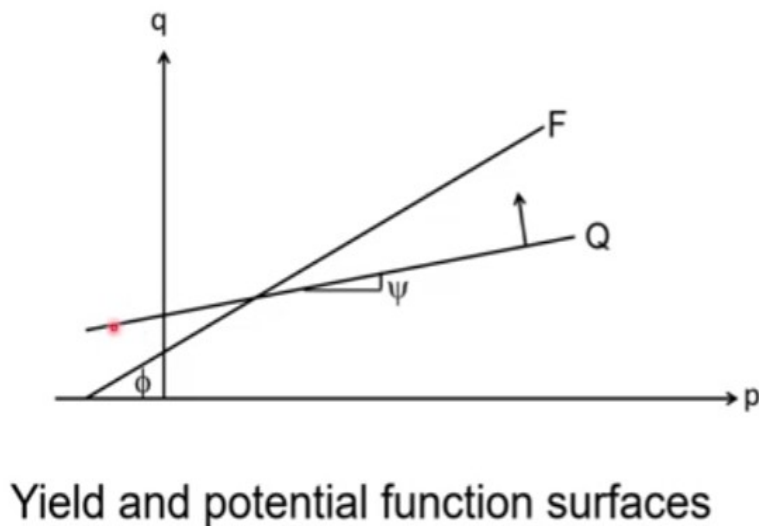

So, if you do this you get del lambda times 1 - sin psi and d epsilon 2p is 0 because we do not have sigma 2 in this potential function and d epsilon 3p is d lambda times dou Q by dou sigma 3 that is d lambda times - 1 - sin psi. So, our total plastic volumetric strain is a d epsilon 1p + d epsilon 2p + d epsilon 3p that comes to - 2 times d lambda sin psi and the negative sign is actually refers to volume expansion.

And when ψ is greater than 0, we see from the above equation that we will get some plastic volumetric strains. So, and this has a negative sign that means that we will get a expansion and when dilation angle is 0 we will not get any volume expansion the volume strain will be 0.

(Refer Slide Time: 29:19)

So, here we can we see in the pq plot we have one surface F that is the yield surface and the other is the plastic potential surface Q and that has a lesser slope. Actually, we can write Q as just simply $\sigma_1 - \sigma_3 - \sigma_1 + \sigma_3 \sin \psi$. We do not require this $2 c \cos \psi$ because we do not require this term for evaluating our plastic strains. So, we show this Q with a lesser slope but then the intercept could be anything.

It is a non, I have shown with some arbitrary intercept it could be anything but we are not really interested in the intercept for the plastic potential function. We are only interested in the slope of that line.

(Refer Slide Time: 30:20)

q

$\psi=0$

Q

p

- Zero dilation angle & no volume change during plastic straining
- The stress path during constant-mean normal stress method corresponds to $\psi=0$ case – hence, it will not produce any plastic volume changes during yielding process

FEA&CM Lecture-32 21

NPTEL

COURSE

FEA & CM

LEARN MORE

Instructor
Dr. K. Rajagopal

When dilation angle is 0, we get a horizontal plastic potential surface horizontal line and the normal to that is vertical and in fact this normal direction we have seen with the mean normal stress method of correction where we have seen that the stress path that is followed is vertical. It is a vertical line and that is perpendicular to this Q the Q of 0 represents the horizontal surface. So, we can say that our mean normal stress method of correction will not produce any volume strains a plastic volume strains.

(Refer Slide Time: 31:15)

Plastic volume changes

- The strain increments during plastic straining need to be re-written as
- $\{d\epsilon\} = \{d\epsilon\}^e + \{d\epsilon\}^p$
- Only the elastic strain increment produces changes in stresses.
- Elastic strain increments and plastic strain increments are estimated separately to obtain the total strain increment
- An elasto-plastic constitutive matrix needs to be developed that describes the stress-strain relations during the plastic straining

So, we can split the total strain tensor $d\epsilon$ as $d\epsilon = d\epsilon^e + d\epsilon^p$ and only the elastic volume elastic strains will produce some stresses and the plastic strains do not produce any stresses or stress increments. And we can write elastic strain increment and the plastic strain increment separately because we have two separate equations. And then we can get the total strain increment $d\epsilon$ as $d\epsilon = d\epsilon^e + d\epsilon^p$.

$$\{d\epsilon\} = \{d\epsilon\}^e + \{d\epsilon\}^p$$

And so based on this we can develop an elastoplastic constitutive matrix.

(Refer Slide Time: 32:10)

Elastic-Plastic constitutive Matrix

During plastic flow, $\{d\sigma\} = [D^{ep}]\{d\epsilon\}$

What is $[D^{ep}]$? (this needs to be derived from fundamentals)

$$\{d\epsilon\} = \{d\epsilon\}^e + \{d\epsilon\}^p$$

As plastic strains do not change the stress state,

$$\{d\sigma\} = [D^e]\{d\epsilon - d\epsilon^p\}$$

And during the plastic flow, $d\sigma$ is D^{ep} times $d\epsilon$ and D^{ep} is the elastoplastic constitutive matrix and $d\epsilon$ is $d\epsilon^e + d\epsilon^p$ and because our plastic strains do not involve any change in the stress state, we can write $d\sigma$ is D^e multiplied by $d\epsilon - d\epsilon^p$ because our this is your elastic strain increment multiplied by elastic constitutive matrix is your incremental stresses.

During plastic flow, $\{d\sigma\} = [D^{ep}].\{d\epsilon\}$

What is $[D^{ep}]$? (this needs to be derived from fundamentals)

$$\{d\epsilon\} = \{d\epsilon^e\} + \{d\epsilon^p\}$$

As plastic strains do not change the stress state,

$$\{d\sigma\} = [D^e].\{d\epsilon - d\epsilon^p\}$$

(Refer Slide Time: 32:57)

Yield function & its change during plastic flow

$$F(\sigma, h, \epsilon_p) = \text{Constant}$$

σ =stress tensor, h =hardening factor, ϵ_p =plastic strains

ϵ_p & h are interdependent

During plastic flow, $dF=0$ as the yield function value should move along the yield surface

NPTEL
COURSE
FEA & CM
LEARN MORE
<https://nptel.ac.in/>
Instructor
Dr. K. Rajagopal

FEA&CM Lecture-32 24

And in general, we can write the yield function as actually it should be constant. See during the plastic flow the yield function is constant the yield function could be a function of stresses and then the hardening factor h and ϵ_p and of course we also have the strength properties that have not listed. But the strength properties are we treat them as constants so we are not going to evaluate their derivatives.

Yield function & its change during plastic flow

$$F(\sigma, h, \epsilon_p) = 0$$

σ =stress tensor, h =hardening factor, ϵ_p =plastic strains

ϵ_p & h are interdependent

During plastic flow, $dF=0$ as the yield function value should move along the yield surface

And σ is the stress tensor h is the hardening factor the ϵ_p is the plastic strains and ϵ_p and h are interdependent because the hardening and then the plastic strains they are related to each other and during the plastic flow the dF is 0, the change in the if F is constant, we can say dF is 0. That is the change in the yield function 0 during the plastic flow because our stress state is moving along the yield surface.

(Refer Slide Time: 34:28)

Yield function & its change during plastic flow
During plastic flow, $dF=0$ as the yield function value should move along the yield surface

$$dF = 0 \Rightarrow \frac{\partial F}{\partial \sigma} \{d\sigma\} + \frac{\partial F}{\partial h} \frac{\partial h}{\partial \epsilon^p} \{d\epsilon^p\}$$

$$\{a_f\} = \frac{\partial F}{\partial \sigma} \qquad \{a_f\} = \frac{\partial F}{\partial \sigma} = \begin{Bmatrix} \frac{\partial F}{\partial \sigma_{xx}} \\ \frac{\partial F}{\partial \sigma_{yy}} \\ \frac{\partial F}{\partial \sigma_{xy}} \end{Bmatrix}$$

$$\{d\epsilon_p\} = d\lambda \frac{\partial Q}{\partial \sigma} = d\lambda \{a_q\}; \quad \{a_q\} = \frac{\partial Q}{\partial \sigma}$$

$\{a_f\}$ and $\{a_q\}$ are called as flow vectors which provide the normal directions to the respective surfaces F & Q

And $dF=0$ means $dF = \frac{\partial F}{\partial \sigma} d\sigma + \frac{\partial F}{\partial h} dh + \frac{\partial F}{\partial \epsilon_p} d\epsilon_p$ by using the chain rule we can write like this. And our in this $\frac{\partial F}{\partial \sigma}$ is basically the normal yield surface and that let us designate with an a_f that is a vector $\frac{\partial F}{\partial \sigma}$ by those $\frac{\partial F}{\partial \sigma}$ and $d\epsilon_p$ is $d\lambda \frac{\partial Q}{\partial \sigma}$. And that is d

lambda times a q, a q is dou Q by dou sigma and a f is dou F by dou sigma for a simple plane strain case.

Yield function & its change during plastic flow

During plastic flow, $dF=0$ as the yield function value should move along the yield surface

$$dF = 0 \Rightarrow \frac{\partial F}{\partial \sigma} \{d\sigma\}_\sigma + \frac{\partial F}{\partial h} \frac{\partial h}{\partial \epsilon^p} \{d\epsilon^p\}$$

$$\{a_f\} = \frac{\partial F}{\partial \sigma} \qquad \{a_f\} = \frac{\partial F}{\partial \sigma} = \begin{Bmatrix} \frac{\partial F}{\partial \sigma_{xx}} \\ \frac{\partial F}{\partial \sigma_{yy}} \\ \frac{\partial F}{\partial \sigma_{xy}} \end{Bmatrix}$$

$$\{d\epsilon_p\} = d\lambda \frac{\partial Q}{\partial \sigma} = d\lambda \{a_q\}; \quad \{a_q\} = \frac{\partial Q}{\partial \sigma}$$

$\{a\}_f$ and $\{a\}_q$ are called as flow vectors which provide the normal directions to the respective surfaces F & Q

It is dou F by dou sigma xx dou F by dou sigma yy and dou F by dou sigma xy and our a f and a q are called as the flow vectors which provide the normal direction to the respective yield surfaces F and Q.

(Refer Slide Time: 35:45)

$$dF = 0 \Rightarrow \{a_f^T\} \{d\sigma\} + \frac{\partial F}{\partial h} \frac{\partial h}{\partial \epsilon^p} \{d\epsilon_p\} = \{a_f^T\} \{d\sigma\} + \frac{\partial F}{\partial h} \frac{\partial h}{\partial \epsilon^p} d\lambda \{a_q\} = 0$$

$$\{a_f^T\} \{d\sigma\} = - \frac{\partial F}{\partial h} \frac{\partial h}{\partial \epsilon^p} d\lambda \{a_q\} = H d\lambda$$

$$H = - \frac{\partial F}{\partial h} \frac{\partial h}{\partial \epsilon^p} \{a_q\}$$

$$\{d\epsilon\} = \{d\epsilon_e\} + \{d\epsilon_p\} = [D_e]^{-1} \{d\sigma\} + d\lambda \frac{\partial Q}{\partial \sigma}$$

Multiplying both LHS & RHS by $\{a_f^T\}[D_e]$ and noting that $[D_e][D_e]^{-1}$ is a unit matrix,

$$\{a_f^T\}[D_e]\{d\epsilon\} = \{a_f^T\}\{d\sigma\} + \{a_f^T\}[D_e]d\lambda \{a_q\}$$

And during the plastic flow because our F is constant and dF is 0 and we have already written that that is a f transpose d sigma + dou F by dou h dou h by dou epsilon p d epsilon p and d epsilon p can be written as d lambda times a q this is 0 and let us set a f transpose d sigma. See

by equating this to 0 we get a f transpose d sigma is - dou F by dou h dou h by dou epsilon p d lambda times a q and let us set all this quantity to some constant h.

So, that our writing becomes more simpler so a f transpose d sigma can be written as some h multiplied by d lambda and if you see this a f transpose d sigma is a scalar quantity because it is actually it is a vector product transpose of this vector a f and multiplied by d sigma. So, actually our H is a constant value and d lambda is also a constant value. So, that product is equal to a f transpose d sigma and our this is actual.

$$dF = 0 \Rightarrow \{a_f^T\} \{d\sigma\} + \frac{\partial F}{\partial h} \frac{\partial h}{\partial \epsilon_p} \{d\epsilon_p\} = \{a_f^T\} \{d\sigma\} + \frac{\partial F}{\partial h} \frac{\partial h}{\partial \epsilon_p} d\lambda \{a_q\} = 0$$

$$\{a_f^T\} \{d\sigma\} = - \frac{\partial F}{\partial h} \frac{\partial h}{\partial \epsilon_p} d\lambda \{a_q\} = H d\lambda$$

$$H = - \frac{\partial F}{\partial h} \frac{\partial h}{\partial \epsilon_p} \{a_q\}$$

$$\{d\epsilon\} = \{d\epsilon_e\} + \{d\epsilon_p\} = [D_e]^{-1} \{d\sigma\} + d\lambda \cdot \partial Q / \partial \sigma$$

Multiplying both LHS & RHS by $\{a_f^T\} [D_e]$ and noting that $[D_e] \cdot [D_e]^{-1}$ is a unit matrix,

$$\{a_f^T\} [D_e] \{d\epsilon\} = \{a_f^T\} \{d\sigma\} + \{a_f^T\} [D_e] d\lambda \{a_q\}$$

This is our consistency equation dF of 0 and d epsilon the total strain increment is d epsilon e + d epsilon p and that we can write as d inverse times d sigma that is D elastic inverse times d sigma + d lambda times dou Q by dou sigma. And we can multiply both left hand side and right-hand side by a f transpose D e and D e times D e inverse is unit vector a unit matrix one. So, a f transpose D e times d epsilon is a f transpose d sigma that is D e times d epsilon e is d sigma + a f transpose D e d lambda times a q, a q is our dou Q by dou sigma.

(Refer Slide Time: 38:41)

$$\{a_f^T\}[D_e]\{d\varepsilon\} = \{a_f^T\}\{d\sigma\} + \{a_f^T\}[D_e]d\lambda\{a_q\}$$

By substituting $\{a_f^T\}\{d\sigma\} = H d\lambda$ in the above equation,

$$\begin{aligned} \{a_f^T\}[D_e]\{d\varepsilon\} &= H d\lambda + \{a_f^T\}[D_e]d\lambda\{a_q\} \\ \Rightarrow d\lambda &= \frac{\{a_f^T\}[D_e]\{d\varepsilon\}}{H + \{a_f^T\}[D_e]\{a_q\}} \end{aligned}$$

FEA&CM Lecture-32

27

And so, we can write this equation as a f transpose D e times d epsilon is a f transpose d sigma + a f transpose D e d lambda times a q and our a f transpose d sigma was earlier written as some constant hits multiplied by d lambda. So, if you substitute this that in this equation and then now, we can determine the d lambda is as a f transpose D e times d epsilon divided by H + a f transpose D e times a q.

$$\{a_f^T\}[D_e]\{d\varepsilon\} = \{a_f^T\}\{d\sigma\} + \{a_f^T\}[D_e]d\lambda\{a_q\}$$

By substituting $\{a_f^T\}\{d\sigma\} = H d\lambda$ in the above equation,

$$\begin{aligned} \{a_f^T\}[D_e]\{d\varepsilon\} &= H d\lambda + \{a_f^T\}[D_e]d\lambda\{a_q\} \\ \Rightarrow d\lambda &= \frac{\{a_f^T\}[D_e]\{d\varepsilon\}}{H + \{a_f^T\}[D_e]\{a_q\}} \end{aligned}$$

(Refer Slide Time: 39:31)

Now, we can utilize $d\lambda$ for estimating the plastic strain increments $\{d\epsilon_p\}$

$$\{d\sigma\} = [D_e]\{d\epsilon - d\epsilon_p\} = [D_e]\{d\epsilon\} - d\lambda[D_e]\{a_q\}$$

By substituting for $d\lambda$ in the above equation, we can write the incremental strains during plastic flow as,

$$\begin{aligned} \{d\sigma\} &= [D^{ep}]\{d\epsilon\} \\ [D^{ep}] &= [D^e] - \frac{[D_e]\{a_f^T\}[D_e]\{a_q\}}{H + \{a_f^T\}[D_e]\{a_q\}} \end{aligned}$$

In the above $[D_{ep}]$ is an unsymmetric matrix as $\{a_f\}$ and $\{a_q\}$ are different if $\phi \neq \psi$

In the above, denominator is a scalar $\{1 \times 3\}\{3 \times 3\}\{3 \times 1\} = 1$
 Numerator: $\{3 \times 3\}\{1 \times 3\}\{3 \times 3\}\{3 \times 1\} = \{3 \times 1\}$, $\{1 \times 3\} = \{3 \times 3\}$ matrix for plane stress/plane strain conditions

And so now we are writing during the plastic straining $d\sigma$ is the elastic times $d\epsilon - d\epsilon_p$ that is D_e times $d\epsilon - d\epsilon_p$ is $d\lambda$ times a_q and so if you substitute that your $d\sigma$ is a D_e times $d\epsilon - d\lambda D_e$ times a_q and our $d\sigma$ is ultimately we want to know what is elastic plastic constitutive matrix $d\epsilon_p$ $d\epsilon$. So, from this see previously we had determined the $d\lambda$ and server $d\sigma$ is a sum matrix multiplied by $d\epsilon$.

And that matrix is a $D_{elastoplastic}$ and by substituting all these parameters we get a $d_{elastoplastic}$ is D_e minus all this quantity D_e times $a_f^T D_e a_q$ divided by $H + a_f^T D_e a_q$ is actually this a_f^T and a_q these are the derivatives of the yield function f with respect to different stress components. And in general, our elastoplastic constitutive matrix is unsymmetric because our a_f and a_q are different.

$$\{d\sigma\} = [D_e]\{d\varepsilon - d\varepsilon_p\} = [D_e]\{d\varepsilon\} - d\lambda[D_e]\{a_q\}$$

By substituting for $d\lambda$ in the above equation, we can write the incremental strains during plastic flow as,

$$\{d\sigma\} = [D^{ep}]\{d\varepsilon\}$$

$$[D^{ep}] = [D^e] - \frac{[D_e]\{a_f^T\}[D_e]\{a_q\}}{H + \{a_f^T\}[D_e]\{a_q\}}$$

In the above $[D_{ep}]$ is an unsymmetric matrix as $\{a_f\}$ and $\{a_q\}$ are different if $\phi \neq \psi$

In the above, denominator is a scalar $\{1 \times 3\}(3 \times 3)\{3 \times 1\} = 1$
 Numerator: $[3 \times 3]\{1 \times 3\}[3 \times 3]\{3 \times 1\} = [3 \times 1] \cdot [1 \times 3] = [3 \times 3]$ matrix for plane stress/plane strain conditions

Because a f is a $\text{dof } F$ by $\text{dof } \sigma$ whereas a q is $\text{dof } Q$ by $\text{dof } \sigma$ and in general the friction angle and dilation angle are not the same. So, we can actually look at what these the dimensions of these terms represent a f transpose is 1×3 vector. Now this is for a plane strain or a plane stress case and D elastic is 3×3 a q is 3×1 that entire product is 1. And if you look at the numerator D_e is a 3×3 matrix a f transpose is 1×3 vector D_e is 3×3 a q is 3×1 .

And we get a 3×3 matrix that is corresponding to your constitutive matrix for plane stress and plane strain.

(Refer Slide Time: 42:27)

$$\{d\sigma\} = [D^{ep}]\{d\varepsilon\}$$

$$[D^{ep}] = [D^e] - \frac{[D_e]\{a_f^T\}[D_e]\{a_q\}}{H + \{a_f^T\}[D_e]\{a_q\}}$$

$$[K] = \int_V [B]^T [D_{ep}] [B] dv$$

Analysis procedure:

- Stiffness matrix of the system is formulated using the elastic-plastic constitutive matrix $[D^{ep}]$ during plastic flow.
- When $F < 0$, $[D^{ep}] = [D^e]$
- If the loading is applied in very small increments, the calculated stresses follow along the yield surface
- If the stress state exceeds the yield surface ($F > 0$), the stresses are corrected back to the yield surface along the flow direction (normal to the plastic potential function)

And our in general during the plastics training we can write $d\sigma$ as D elastoplastic times $d\epsilon$ where D elastoplastic is D elastic - this whole quantity. And we can evaluate the stiffness matrix K as B transpose D elastoplastic. So, instead of D_e we write D_{ep} and so B transpose D_{ep} B integrated of the volume and this will give us our stiffness matrix for the continuum during the elastic plastic state.

$$\{d\sigma\} = [D^{ep}]\{d\epsilon\}$$

$$[D^{ep}] = [D^e] - \frac{[D_e]\{a_f^T\}[D_e]\{a_q\}}{H + \{a_f^T\}[D_e]\{a_q\}}$$

$$[K] = \int_V [B]^T [D_{ep}] [B] dv$$

And the stiffness matrix can be formulated using D_{ep} and when F is less than 0 that is when the soil is in the elastic state the elastoplastic is just simply D_e and then we need to apply the load in very small increments so that we can follow the stress we can follow the yield surface. And so, but then we cannot always do that like we apply some arbitrary stress increments and then it is more preferable to correct the stress state back to the yield surface rather than using very very small stress and strain increments.

Save the stress stating the exceeds the yield surface with F greater than 0. The stresses are corrected back to the surface along the flow direction normal to the plastic potential function.

Instructor
Dr. K. Rajagopal

And it is something like this actually this is our Mohr circle that has crossed the yield limit and we have another Mohr circle that is within the yield surface. It is just simply tangent and if you look at the pq diagram that is normal to this to this Q, Q is our potential function.

(Refer Slide Time: 44:42)

Mohr Coulomb yield surface in terms of stresses

$$\sigma_{1f} = \frac{1 + \sin \phi}{1 - \sin \phi} \sigma_3 + \frac{2.c.\cos \phi}{1 - \sin \phi}$$

$$F = (\sigma_1 - \sigma_3) - (\sigma_1 + \sigma_3) \sin \phi - 2.c.\cos \phi$$

$$\sigma_{1,3} = \frac{\sigma_{xx} + \sigma_{yy}}{2} \pm \sqrt{\left(\frac{\sigma_{yy} - \sigma_{xx}}{2}\right)^2 + \sigma_{xy}^2}$$

$$F = \sqrt{(\sigma_{yy} - \sigma_{xx})^2 + 4\sigma_{xy}^2} - (\sigma_{xx} + \sigma_{yy}) \sin \phi - 2.c.\cos \phi$$

For axisymmetric case, σ_m , σ_{zz} and σ_{rz} are used in the above equations. In most cases, circumferential stress σ_θ will be equal to radial stress σ_r

COURSE

FEA & CM

Instructor
Dr. K. Rajagopal

And our Mohr Coulomb yield surface can be written like this sigma 1 f is 1 + sin phi by 1 - sin phi sigma 3 + 2 c cosine phi by 1 - sin phi and in terms of stresses we can write like this and for the axisymmetric case instead of sigma xx we have sigma rr and instead of sigma yy we have sigma zz and instead of having sigma xy we have sigma r theta r z and then we have other sigma theta that is the circumferential stress.

Mohr Coulomb yield surface in terms of stresses

$$\sigma_{1f} = \frac{1 + \sin \phi}{1 - \sin \phi} \sigma_3 + \frac{2.c.\cos \phi}{1 - \sin \phi}$$

$$F = (\sigma_1 - \sigma_3) - (\sigma_1 + \sigma_3) \sin \phi - 2.c.\cos \phi$$

$$\sigma_{1,3} = \frac{\sigma_{xx} + \sigma_{yy}}{2} \pm \sqrt{\left(\frac{\sigma_{yy} - \sigma_{xx}}{2}\right)^2 + \sigma_{xy}^2}$$

$$F = \sqrt{(\sigma_{yy} - \sigma_{xx})^2 + 4\sigma_{xy}^2} - (\sigma_{xx} + \sigma_{yy}) \sin \phi - 2.c.\cos \phi$$

(Refer Slide Time: 45:26)

J_1 & J_{2d} in terms of stresses

$$J_1 = \sigma_1 + \sigma_2 + \sigma_3 \equiv \sigma_{xx} + \sigma_{yy} + \sigma_{zz}$$

$$J_{2d} = \frac{1}{2} s_{ij} : s_{ij} = \frac{1}{2} (s_{xx}^2 + s_{yy}^2 + s_{zz}^2 + 2s_{xy}^2 + 2s_{yz}^2 + 2s_{zx}^2)$$

$$= \frac{1}{6} \left\{ (\sigma_{xx} - \sigma_{yy})^2 + (\sigma_{yy} - \sigma_{zz})^2 + (\sigma_{zz} - \sigma_{xx})^2 \right\} + s_{xy}^2 + s_{yz}^2 + s_{zx}^2$$

(Refer Slide Time: 45:32)

Principal stresses for 3-d stress tensor

The three principal stresses are obtained as the three roots of the stress tensor as,

$$\begin{vmatrix} \sigma_{xx} - \lambda & \sigma_{xy} & \sigma_{xz} \\ \sigma_{xy} & \sigma_{yy} - \lambda & \sigma_{yz} \\ \sigma_{xz} & \sigma_{yz} & \sigma_{zz} - \lambda \end{vmatrix} = 0$$

Cubic equation is obtained from the determinant of the above matrix equated to zero.

I think this we have already seen all these J 1 J 2d definitions and this also we have seen earlier.
(Refer Slide Time: 45:37)

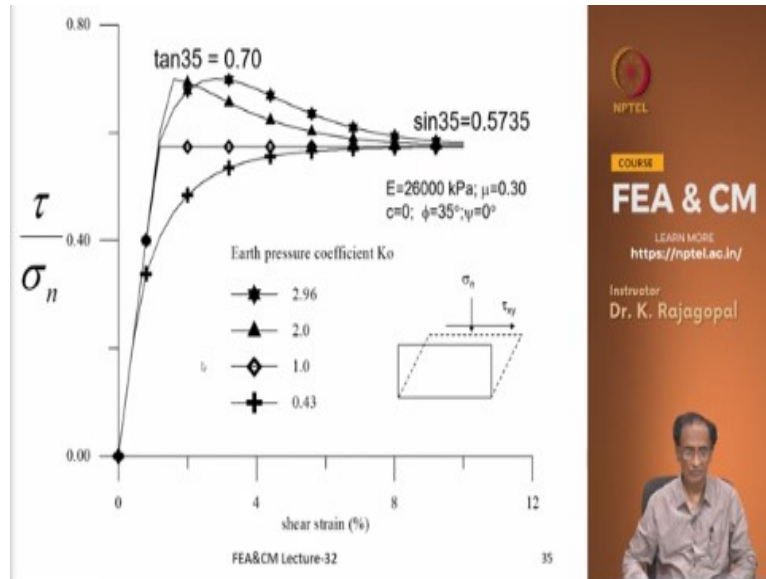

- The D-matrix during plastic flow can be formulated using the equations derived.
- The D-matrix for some simple cases like elastic-plastic joint element & for Von-Mises model will be derived in a step by step manner to describe this procedure
- Interesting limit solutions can be obtained from element tests (tests performed on single elements or just on constitutive equations)

So, the D matrix during the plastic flow can be formulated using the previously derived equations and we will see how to determine the D matrix for very simple cases like the next class I will demonstrate step by step how to determine the elastoplastic constitutive matrix. Then we can also do these calculations for the Von-Mises model. Von-Mises model we will see is actually it is a very simple cylindrical surface and finding normal to that is very simple.

But then when it comes to our Mercola model, we will see that it is very difficult the reason we will see later. And we can get very interesting limit solutions from after implementing this elastoplastic analysis.

(Refer Slide Time: 46:42)

And here we see the stress strain response of the direction of the simple shear test the properties are the young's modulus is at 26000, poisons ratio is 0.3 c is 0, phi is 35 degrees and dilation angle is 0. And the dilation angle 0 means the soil is non-dilatant and I have taken a cubicle sample and then applied the simple shear strain conditions at four different confirm K 0 values K 0 of 0.43 that is 1 - sin phi because our friction angle is 35 degrees 1 - sin phi is 0.43 sin 35 is 0.57 and K 0 of 1 K 0 of 2 and K 0 of 2.96.

So, all these very high K 0 values what we do is we can initiate them by applying with the dummy poisons ratio as Mu is K 0 by 1 + K 0 and then when we are doing the shearing, we reset the poisons ratio back to 0.3. And say if you perform the simple shear test, we get very interesting results with the K 0 of 0.43 the tau is increasing and gradually it is increasing to sin 35 because our dilation angle is 0 and the tau by sigma n is sin phi times cosine psi by 1 - sin phi times sin psi.

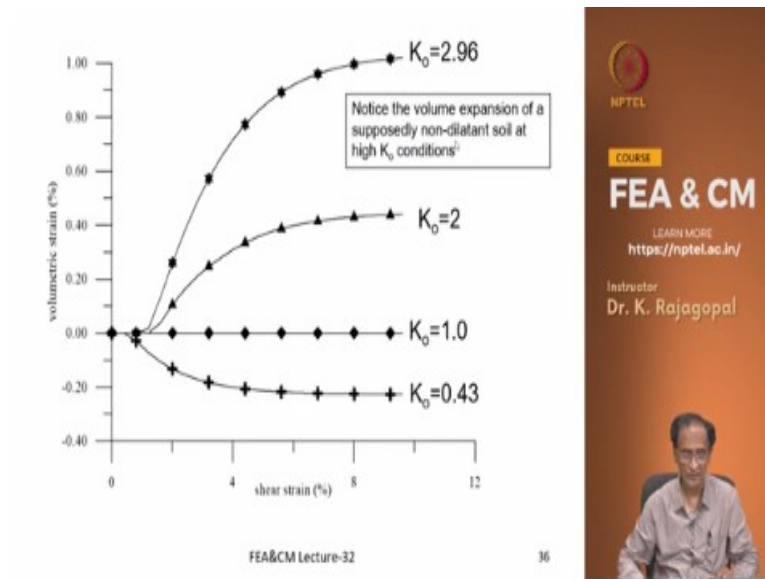

And for a psi of 0 the tau by sigma and max = sin phi that is 0.57 and then when your K 0 is 1 exactly equal to 1 we get a bilinear elastic response. So, with the K 0 of less than 1.43 we get a

nice curved surface like this reaching the asymptotic limit. But then when K_0 is 1 the stress is increased and then it has reached the yield state and then after that the stresses have remained constant.

But if you look at K_0 of 2 and 2.96 the shear stress has gone beyond this limit of $\sin \phi$ it has gone up to $\tan \phi$ $\tan 35$ that is 5.7 then after eating after the shear stress is increased beyond your critical state the shear stress started falling down and with the K_0 of 2.96, we get a very nice peak a curvilinear surface and then after reaching $\tan 35$ the shear stress will go on decreasing with further increase in the shear strain.

And with the K_0 of 2 is actually it is another interesting result the stress has suddenly increased to $\tan 5$ level $\tan 35$ level and then after that the stresses have fallen down. Then at a very large shear strain all the four responses are corresponding to $\sin \phi$ τ by σ_n of $\sin \phi$. That is what we discussed as the critical state or the critical state both the dense sand and the loose sand they have the same strength because all the interlocks have broken and both behave in a similar manner. Because your void ratio tends to the same value at a large critical state.

(Refer Slide Time: 51:01)

And if you look at the volume strain graphs you get very interesting results with the K_0 of 0.43 there is volume compression and with the K_0 of 1 is absolutely no volume change. The plastic straining happen without any volume change and with the K_0 of 2 and 2.96 initially during the

elastic state there is no volume change and then after the plasticity started there is a volume expansion and then at a critical state the volume has remained constant.

And this volume expansion is actually it is happening for a so-called non-dilatant soil with a dilation angle of 0. So, that has happened because our initial K_0 is very high and you get when the initial stresses are dispersed you get volume expansion. That is what we see here and this is similar to your highly interlocked soil and as the interlocks are breaking you get volume expansion.

That is what we see here as the K_0 are the K gradually reduces from K from say 2.96 to 0.43 because our strength of the soil is ϕ . And the K_0 of $1 - \sin \phi$ is consistent with the plastic equilibrium. So, it will come back then once that happens this is what we have. We have constant volume condition.

(Refer Slide Time: 52:56)

Procedure for stress correction is explained in the paper *Elasto-Plastic Stress Analysis: Generalization for Various Constitutive Relations including Strain softening*, Nayak, G.C. & Zienkiewicz, O.C. (1972), *Int. National J. for Numerical Methods in Geomechanics*, Vol. 5, 113-135.

It is difficult to explain the entire procedure but easy to understand by writing down the equations and examining the different steps.

And more details of this derivation and how to do these computations are explained in the paper by Nayak and Zienkiewics 1972 and this paper is titled as elastoplastic stress analysis and generalization for various constitute relations including strain softening. I have tried to explain some part of this paper through this lecture have not have skipped some mathematical details because they become too complicated.

But then for some simple cases I will do step by step calculations so that we are not carried away by those complicated mathematical equations, that we will see in the next class. And is actually these equations could be very long and so it is a difficult to explain but if you sit down with that paper and work out all these calculations they appear to be not so difficult.

(Refer Slide Time: 54:07)

The equations are a bit complicated to visualize.

We will examine this in more detail step by step with respect to elastic-plastic joint element which is more simpler.

FEA&CM Lecture-32

38

FEA&CM Lecture-32

39

So, the application of this theory for the bearing capacity problem with the dilation angle of 0 and the dilation angle of 10 you get two different responses with a higher dilation angle we get a higher bearing capacity. And that is what we see here on the x axis we have the bearing pressure and then the y axis we have the settlement.

(Refer Slide Time: 54:38)

And with the dilation angle of 10 degrees there is a nice volume expansion or the ground heaving.

(Refer Slide Time: 54:48)

And with the dilation angle of 0 you see these arrows are very small compared to the size of the arrows with the dilation angle of 10 degrees.

(Refer Slide Time: 54:58)

Dilation angle = 10°

Dilation angle = 0°

Navigation icons

FEA&CM Lecture-32

42

This is the comparison on the left hand side we have dilation angle of 10 degrees on the right hand side we have a dilation angle of 0.

Classical Plasticity Theories

- Tresca
- Von Mises
- Mohr-Coulomb
- Drucker-Prager

Navigation icons

FEA&CM Lecture-32

43

And this generalized procedure we can extend to any type of plasticity theories some of the classical plasticity theories are Tresca, Von Mises, Mohr-Coulomb and Drucker-Prager.

(Refer Slide Time: 55:29)

Tresca Yield criterion

- Yielding of a material begins when the maximum shear stress at a point reaches a critical value.
- In 3-d space, mathematically, this yield criterion can be written as,
- $\max(\frac{1}{2}|\sigma_1 - \sigma_2|, \frac{1}{2}|\sigma_2 - \sigma_3|, \frac{1}{2}|\sigma_3 - \sigma_1|) = k$
- The effect of hydrostatic pressure (confining pressure) on the yield strength is not considered

FEACM Lecture 32

44

Tresca is one of the earliest models in which we say that material starts yielding when the maximum shear stress reaches a particular limit or a critical value. And in the three-dimensional space we can write this as Tresca yield criterion as maximum of $\frac{\sigma_1 - \sigma_2}{2}$ or $\frac{\sigma_2 - \sigma_3}{2}$ or $\frac{\sigma_3 - \sigma_1}{2}$. This k is some yield limit and actually when we do the triaxial compression test, we plot the Mohr circle and then the radius is defined as the cohesive strength.

In 3-d space, mathematically, this yield criterion can be written as,

$$\max(\frac{1}{2}|\sigma_1 - \sigma_2|, \frac{1}{2}|\sigma_2 - \sigma_3|, \frac{1}{2}|\sigma_3 - \sigma_1|) = k$$

And this k is similar to our cohesive strength and in this Tresca model the effect of hydrostatic pressure is not considered. The yield strength is not a function of J_1 .

(Refer Slide Time: 56:30)

Plot of Tresca yield condition on octahedral plane perpendicular to hydrostatic axis

FEACM Lecture-32

43

And say if you plot this in the principal stress space say the if you take a space of sigma 1 and sigma 2 sigma 3 and the droid and hydrostatic axis line and then perpendicular to that we call that as the octahedral plane. And if you plot your Tresca yield surface in the principal stress direction sigma 1, sigma 2, sigma 3 we get a surface something like this. This is an octahedral plane perpendicular to the hydrostatic axis.

(Refer Slide Time: 57:10)

Tresca yield surface in 2-d principal axes space

FEACM Lecture-32

44

And in the 2d space where you have only sigma 1 and sigma 3 and sigma 2 is not considered we get a more simple shape something like this and if you have this type of surface and if I ask you to determine the normal to this yield surface at the corners, how do we do? We have no idea

because we know how to calculate the normal along this vertical surface or horizontal surface or inclined surface but then at this point it could be infinite.

It is there are too many directions we can draw that means that we will have some we should expect some numerical difficulties.

(Refer Slide Time: 58:02)

Tresca Yield Condition

- $(\sigma_1 - \sigma_3)/2 = c$
- $F = \sigma_1 - \sigma_3 - 2c$
- $Q = F$ as friction angle=dilation angles=0 ($\phi=\psi=0$)
- Leads to associated plasticity flow rule. Can be obtained from Mohr-Coulomb yield theory by setting ϕ & ψ to zero.
- Will not simulate shear induced dilation.
- Independent of intermediate principal stress (σ_2); suitable only for 2-d or axisymmetric problems
- Tensile stresses need separate control

NIPTEL

Instructor
Dr. K. Rajagopal

FEA&CM Lecture-32 47

And in the pq space our Tresca yield criterion is very simple it says it is a line it is a horizontal line and we can write $\sigma_1 - \sigma_3$ by $2c$ the c is the cohesive strength and the yield function F can be written as $\sigma_1 - \sigma_3 - 2c$ and there is no friction angle ϕ and the c is not a function of hydrostatic pressure. Whatever may be the hydrostatic pressure or the strength of the soil is not going to change.

$$\begin{aligned}
 &(\sigma_1 - \sigma_3)/2 = c \\
 &F = \sigma_1 - \sigma_3 - 2c \\
 &Q = F \text{ as friction angle=dilation angles=0 } (\phi=\psi=0)
 \end{aligned}$$

And in this particular case both dilation angle and the friction angle are 0 we can say it is an associated plasticity rule. But then it is a misleading one because you will not get any plastic volumetric strains because our dilation angle is 0. And we see that the effect of σ_2 is absent we do not have the effect of the intermediate principle stresses σ_2 . So, this particular Tresca yield criterion is good for 2d or axisymmetric problems.

And as we discussed earlier, we can plot this Mohr circle and without exceeding the yield limit either in the compression space or in the tension space. So, we require some control on the tensile stresses so whenever you develop two very large tensile stresses, we need to correct the stresses so that we end up in the compression space.

Mohr Coulomb yield condition

$$\sigma_{1f} = \frac{1 + \sin \phi}{1 - \sin \phi} \sigma_3 + \frac{2.c.\cos \phi}{1 - \sin \phi}$$

$$F = (\sigma_1 - \sigma_3) - (\sigma_1 + \sigma_3) \sin \phi - 2.c.\cos \phi$$

Suitable only for two-dimensional or axisymmetric problems as this theory is independent of intermediate principal stress σ_2
If $\phi=0$, Mohr Coulomb model simplifies to Tresca yield condition

The Mohr Coulomb yield surface is something like this. This is in terms of c and phi and the yield function F can be written like this and if you substitute friction angle phi of 0, we get back our Tresca yield criterion. So, the Mohr Coulomb yield surface with the phi of 0 is nothing but the Tresca yield criterion.

Mohr Coulomb yield condition

$$\sigma_{1f} = \frac{1 + \sin \phi}{1 - \sin \phi} \sigma_3 + \frac{2.c.\cos \phi}{1 - \sin \phi}$$

$$F = (\sigma_1 - \sigma_3) - (\sigma_1 + \sigma_3) \sin \phi - 2.c.\cos \phi$$

Hexagonal yield surface of Mohr-Coulomb yield theory on the Octahedral plane (approximate shape) – notice the corners

FEA&CM Lecture-32

49

And the octahedral plane the if you plot the Mohr-Coulomb yield surface it will be something like this. It is actually the shape is correct but then the its only approximation and if you want more exact one you refer to any textbook any good textbook. But it is basically it is a hexagonal shape because you have 1, 2, 3, 4, 5, 6 surfaces given for Tresca we had six surfaces. But then that is a regular hexagon and this is a hexagonal it is not exactly hexagon.

(Refer Slide Time: 1:01:01)

Von Mises yield theory

Octahedral shearing stress is used to check for the yielding

$$\tau_{oct} = \sqrt{\frac{2}{3}} J_{2d} = \sqrt{\frac{2}{3}} K \quad \sqrt{J_{2d}} = k$$

$$F = \sqrt{J_{2d}} - k$$

J_{2d} is the 2nd invariant of the deviator stress tensor = $\frac{1}{2} S_{ij} : S_{ij}$

$$J_{2d} = \frac{1}{2} (s_{xx}^2 + s_{yy}^2 + s_{zz}^2 + 2s_{xy}^2 + 2s_{yz}^2 + 2s_{zx}^2)$$

- Originally used for metal plasticity problems. May be applicable for undrained geotechnical problems but not accurate.
- Can be used for 3-dimensional problems

FEA&CM Lecture-32

50

And Von Mises theory is actually the octahedral shearing stress is used and basically, we can say the yield function F is the square root of J 2d - k where k is some constant and J 2d is our second invariant of the deviator stress tensor. And this Von Mises floral was used in the metal plasticity

theories and it is not really applicable for geotechnical problems but it is by experience they have seen that this model is good for unruined problems.

Von Mises yield theory

Octahedral shearing stress is used to check for the yielding

$$\tau_{oct} = \sqrt{\frac{2}{3}J_{2d}} = \sqrt{\frac{2}{3}}\kappa \quad \sqrt{J_{2d}} = k$$

$$F = \sqrt{J_{2d}} - k$$

J_{2d} is the 2nd invariant of the deviator stress tensor = $\frac{1}{2} S_{ij} : S_{ij}$

$$J_{2d} = \frac{1}{2}(s_{xx}^2 + s_{yy}^2 + s_{zz}^2 + 2s_{xy}^2 + 2s_{yz}^2 + 2s_{zx}^2)$$

- Originally used for metal plasticity problems. May be applicable for undrained geotechnical problems but not accurate.
- Can be used for 3-dimensional problems

And the c and k they are not directly related to it they are somehow related to each other that we need to find the relation that we will see later. And because this J_{2d} is involving all the stress components σ_x σ_y σ_z τ_{xy} τ_{yz} τ_{zx} . So, this Von Mises theory can be applied for 3d problems. Whereas the Mohr Coulomb model and Tresca they are only good for two dimensional problems either plane strain or axisymmetric but not for 3d because we do not have the σ_2 .

Plot of Tresca & Von Mises yield condition on octahedral plane perpendicular to hydrostatic axis – normal to Von Mises surface is simple due to smooth surface; normal direction at corners of Tresca surface is difficult to evaluate – more on this will be explained later through handouts

Whereas the Von Mises theory is good for the 3d problems and if you plot the Von Mises is actually get a nice circle it is a circular surface on the octahedral plane and circle means it is a smooth surface so we can easily draw the normal to this von Mises surface.

(Refer Slide Time: 1:03:03)

Drucker-Prager theory

$$\sqrt{J_{2d}} - \alpha J_1 = k$$

$$F = \sqrt{J_{2d}} - \alpha J_1 - k$$

$$J_1 = \sigma_{xx} + \sigma_{yy} + \sigma_{zz}$$

Plane strain conditions

$$\kappa = \frac{3c}{\sqrt{9 + 12 \tan^2 \phi}}$$

$$\alpha = \frac{\tan \phi}{\sqrt{9 + 12 \tan^2 \phi}}$$

Triaxial compression conditions

$$\kappa = \frac{6c \cos \phi}{\sqrt{3}(3 - \sin \phi)}$$

$$\alpha = \frac{2 \sin \phi}{\sqrt{3}(3 - \sin \phi)}$$

And the Drucker Prager theory is a slight extension of the Von Mises and this is the square root of $J_{2d} - \alpha J_1 = k$ where alpha and the k are the yield parameters or the strength parameters. And this the Drucker Prager model is slightly different where in our yielding is controlled by the hydrostatic pressures the J_1 whereas in the Von Mises theory the J_1 was not there. And the alpha and k can be related to c and phi by matching.

Drucker-Prager theory

$$\sqrt{J_{2d}} - \alpha J_1 = k$$

$$F = \sqrt{J_{2d}} - \alpha J_1 - k$$

$$J_1 = \sigma_{xx} + \sigma_{yy} + \sigma_{zz}$$

- Compression stresses are +ve
- This model is applied for analysis of concrete structures
- Suitable for 3-dimensional analysis
- If $\alpha=0$, Von-Mises theory is obtained
- Influence of hydrostatic pressures

Plane strain conditions

$$\kappa = \frac{3c}{\sqrt{9 + 12 \tan^2 \phi}}$$

$$\alpha = \frac{\tan \phi}{\sqrt{9 + 12 \tan^2 \phi}}$$

Triaxial compression conditions

$$\kappa = \frac{6c \cos \phi}{\sqrt{3}(3 - \sin \phi)}$$

$$\alpha = \frac{2 \sin \phi}{\sqrt{3}(3 - \sin \phi)}$$

So, for the plane strain conditions this is the matching and for the triaxial compression test this is the matching. The actual this matching you can find in most of the plasticity textbooks but I am not explaining here because we are not really interested in deriving these equations but we will see the applications. And depending on the problem that you have whether you have a triaxial or axisymmetric or a plane strain case we can relate the c and k say for a friction angle of 0 the k is exactly equal to c for the plane strain case.

Whereas for triaxial compression it is 6 by 3 root 3 see that is a 2 by root 3 so 2 by root 3 means slightly more than 1. So, the k is 2 divided by root 3 times c so, this the Drucker Prager by using the c and the by relating k and alpha to c and phi we can get a good match between the predictions of Drucker Prager and then the Mohr Coulomb models. And the Drucker Prager model is also applicable for three dimensional problems.

And the Drucker Prager model is good for concrete whereas it is not so popular for soil mechanics but although some people use the Drucker Prager model for 3d problems by matching the c and phi to k and alpha like this, this may be my last slide.

(Refer Slide Time: 1:05:43)

- Finding the normal to Tresca & Mohr-Coulomb yield surfaces is numerically complicated
- Special procedures are required as described by Nayak and Zienkiewics (1972)
- Both Von Mises and Drucker Prager theories have smooth conical surfaces in the 3-d space and circle on the Octahedral plane
- Determination of normal directions to the yield surface will be explained through handouts with detailed calculations

FEACM LECTURE-32

33

And see when we do the numerical computations, we see that we cannot easily determine the normal to the Tresca and Mohr coulomb yield surfaces especially at corners. And how do you know that you are at a corner? So, that requires one more parameter theta that I have not explained but you can find in this paper by Nayak and Zienkiewics and both Von Mises and Drucker Prager they have a smooth conical surfaces in the 3d space.

And in the octahedral plane is a circle so drawing a normal to the circle is very simple. And so, this determination of the normal I will explain through handouts and then I will try to reproduce the lines from the computer code. So, that you see how these normals are evaluated. So, this is my last slide. So, thank you very much, if you have any questions, please send an email to this profkr@gmail.com so, thank you very much until we meet next time bye for now.
