Lecture 22:
Natural Number, Divisor

Welcome to the NPTEL MOOC on discrete mathematics. This is the first lecture on number theory. In number theory we study the theory on integers. Integers along with the two operators multiplication and addition and the two constant 0 and one you would see in the module on algebraic structures that form what is called an integral domain? So number theory is the study of this integral domain.

(Refer Slide Time: 1:04)

So in number theory, we deal with a set of integers and operators multiplication in addition along with 0 and one together this form an integral domain.

(Refer Slide Time: 1:37)

For integers $a \neq 0, b$
we say that a divides b
if $\exists x \in \mathbb{Z} (b = ax)$
" $a|b$ " $\neg(a|b) \equiv \underline{\underline{a \nmid b}}$

For two integers a and b where a is not equal to 0. We say that a divides b , if there exists an integer x , so that b equals ax , that is a board multiplying a with some integer x , we would get b that is when we said that a divides b and this is denoted in this [fashion](#) using a vertical bar. This notation asserts that a divides b . The negation of this, that is the negation of a divides b this often written like this across the vertical bar to indicate that a does not divide b .

(Refer Slide Time: 2:43)

$a|b \rightarrow$
 $\forall c \in \mathbb{Z} (a|bc)$

 $b = ax$ for some integer x
for any c
 $b = ax \rightarrow bc = axc$
 $\rightarrow (xc)a \rightarrow a|bc$

So let us see some results related to division if a divides b , then for every c which is an integer it is the case that a divides bc . See [I](#) this is easy to show if a divides b , then b equal to ax for some integer x then for any c we have b equal to ax . Therefore bc equal to ax into c which by associativity of multiplication can be written as xc times a this implies that a divides bc . So that was easy to show.

(Refer Slide Time: 3:42)

if $a|b$ and $b|c$ then $a|c$
"divides" relation is transitive

$a|b \rightarrow$ for some x , $b = ax$
 $b|c \rightarrow$ for some y , $c = by$
 $c = by = axy = (xy)a \rightarrow \underline{a|c}$

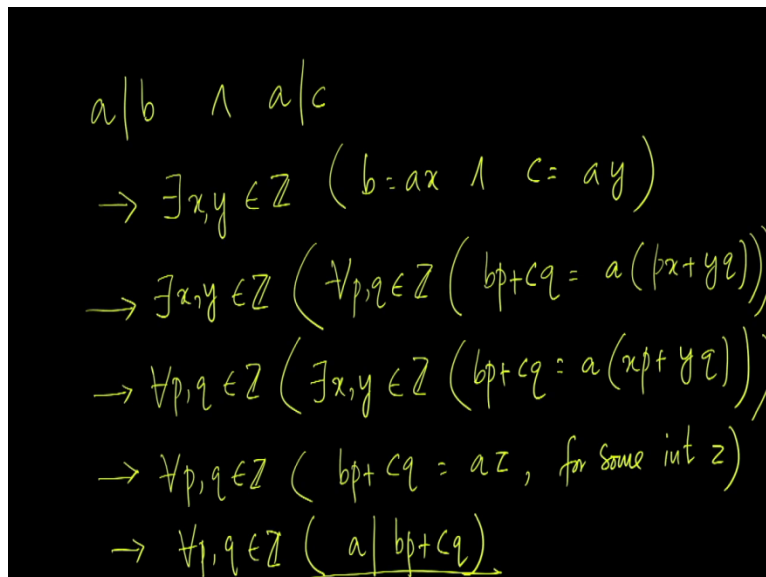

Another ~~result is~~ ~~tussle~~ ~~does~~ this if a divides b and b divides c , then a divides c . In other words, the divides relation is transitive. This is also easy to show, a divides b implies that for some integer x , b equal to ax . Similarly, b divides c implies that for some integer y , c equal to by , therefore c can be written as the product of xy and a which means there is an integer so that a into that integer is c . So that implies that a divides c .

(Refer Slide Time: 4:56)

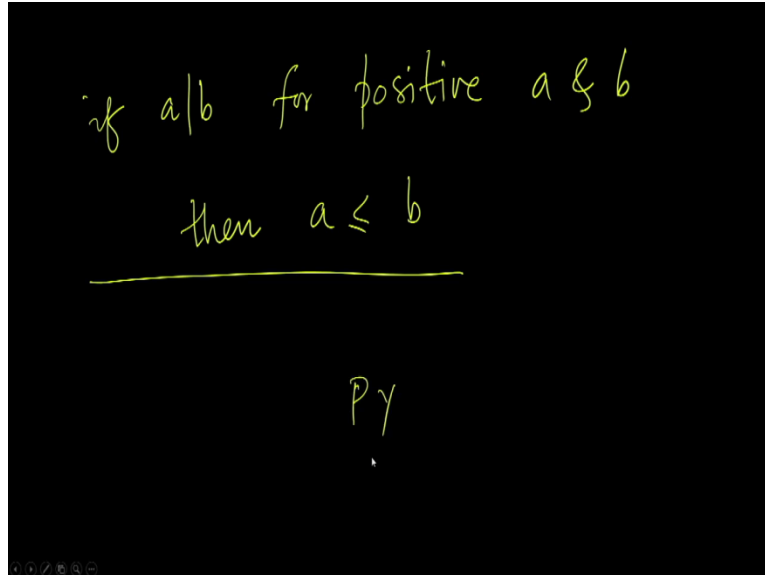

The third result is this if a divides b and a divides c then for any p, q be that are integers, a divides bp plus cq . That is if a divides b and a divides c , then a will be divide any linear combination of b and c , where the linear combination has integer coefficients p and q are the coefficients of the linear combination, these are integers. So any such linear combination of b and c will be divided by a .

(Refer Slide Time: 5:48)

equal to b in the second case we have a equal to minus b . So combining these two we can assert that is a plus or minus b .

(Refer Slide Time: 9:35)

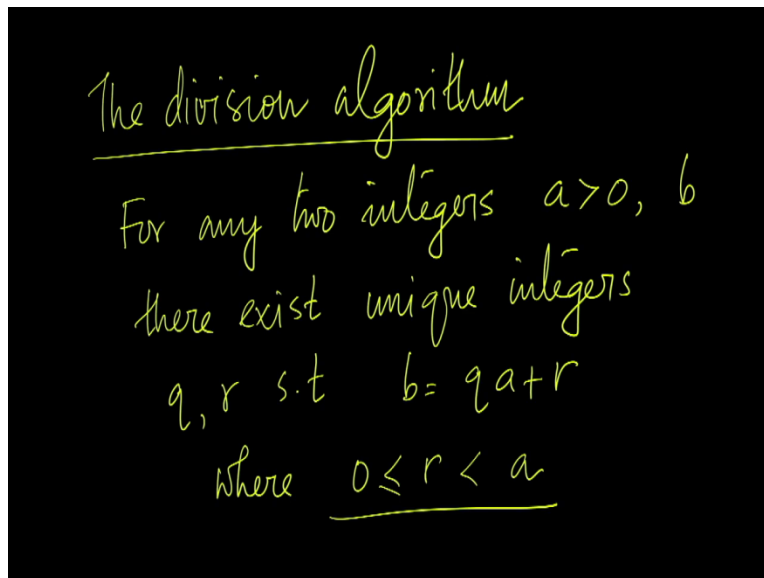

If a divides b for positive a and b then a less than or equal to b prove this yourself.

(Refer Slide Time: 9:59)

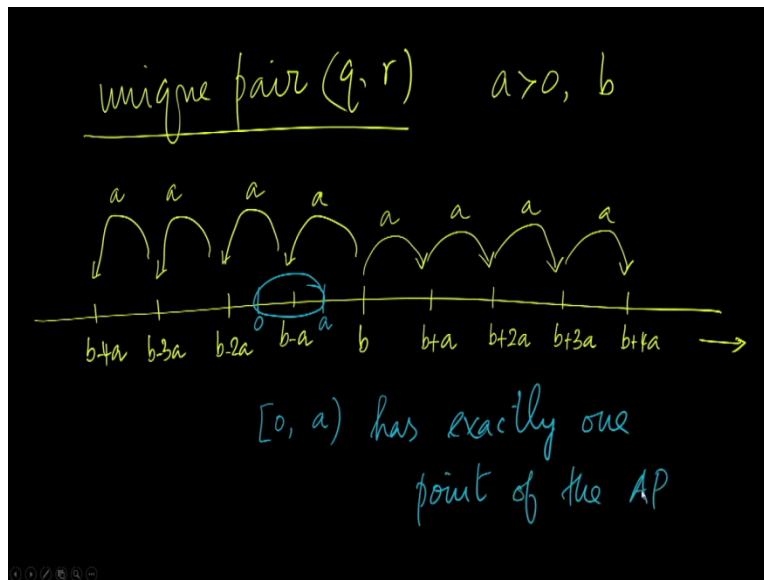

And another property of the divides relation is this if an integer x that is non 0 is given and a divides b then xa divides xb . This also you can try out, so those were some results about their divisibility relation.

(Refer Slide Time: 10:36)

Now let us see what is called the division algorithm. At the heart of this algorithm we have this theorem. For any two integers a and b , where a is greater than 0, b need not be greater than 0 there exist unique integers given r such that b is qa plus r , where 0 is less than or equal to r which is less than a . So when you find such a unique ordered pair q, r q is called the quotient and r is called the remainder.

(Refer Slide Time: 11:50)

So how do we prove that there exists such a unique pair qr ? That is what we want. We consider the real line on this real line consider point b . b is an integer it may be positive or negative and we have a which is greater than 0 . From b let us start marking points that are at distance a . So we get an arithmetic progression b plus a is the next point, b plus $2a$ is the one after that; b plus $3a$ is one after that and so on.

That is going to ~~Let us go into~~ the right side. If you go to the left side we have b minus a , b minus $2a$, b minus $3a$ and so on. So starting from b we are going to the right jumping at a distance of a every time. Similarly, we can also move to the left jumping at a distance of a every time. Now on this real line 0 is somewhere let us say this is where 0 is.

In that case a will be here at a distance of $-a$ from 0 to the right. So let us consider this interval, the interval from 0 to a . You start from b and start jumping at a distance of a either to left or to the right. In one of the directions you would jump into this interval exactly once. That is there will be exactly one point falling in this interval which is within this arithmetic progression. This interval has exactly one point of the, in particular what we need to know is that there is one point.

(Refer Slide Time: 14:26)

(q, r) corresponds to the one point we find.

$$b - qa = r$$
$$\underline{b = qa + r} \quad \underline{0 \leq r < a}$$

Suppose that one point corresponds to q, r , ordered pair q, r corresponds to the one point that we find. Then at this point we have b minus qa equal to r or b equals qa plus r and here 0 less than or equal to r less than a . Now we have to argue that this ordered pair is unique.

(Refer Slide Time: 15:16)

Suppose (q', r') is another such

$$r' \neq r$$

otherwise $q' = q$

$$r' = b - q'a$$

So r' is a nonnegative member of the AP

$0 \leq r'$

Suppose otherwise. Suppose q prime r prime is another such ordered pair. Clearly r prime is not equal to r because otherwise q prime is the same as q and therefore this ordered pair would not

be distinct from the earlier one. So r prime is not equal to r and r prime is b minus q prime a that is because q prime r prime is an ordered pair which satisfies our requirement.

So r prime is a ~~non-negative~~ non-negative member of the a prime that is because we assume that 0 less than or equal to r prime. q prime r prime is another ordered pair where r prime is greater than or equal to 0 .

(Refer Slide Time: 16:29)

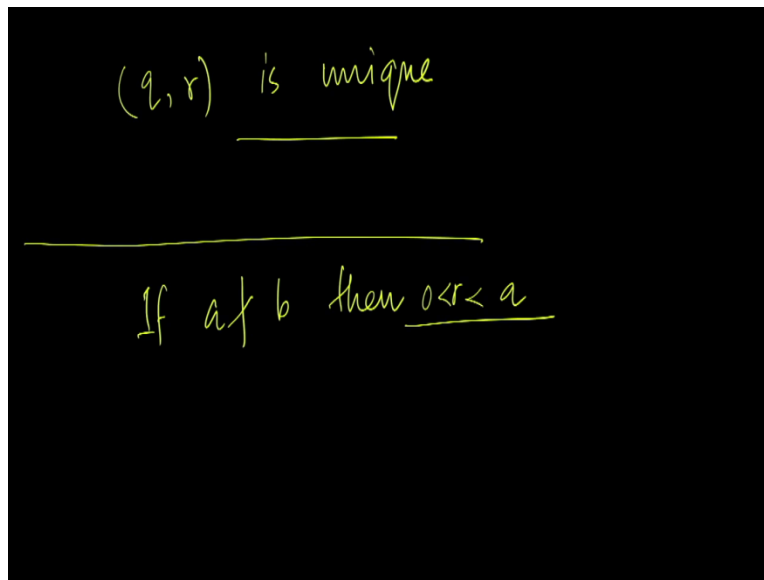

r is the least nonnegative
mem. of the AP

$$r' \geq r + a$$
$$= b - qa + a \geq \underline{a} \checkmark$$

(q', r') s.t. $b = q'a + r'$
and $\underline{0 \leq r' < a}$

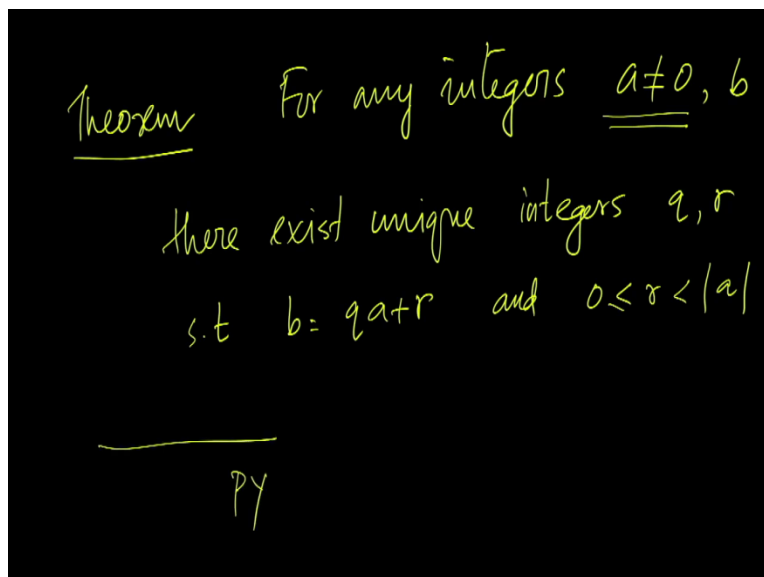

But then r is the least non-negative member of the a ~~prime~~. So r prime is greater than or equal to r plus a . But what is r plus a this is b minus qa plus a . But this is then greater than or equal to a . And therefore our prime will not qualify, because we want like q prime r prime such that b is q prime a plus r prime and 0 less than or equal to r prime less than a . This is violated here. Therefore, there cannot be another ordered pair q prime, r prime.

(Refer Slide Time: 17:30)

So q, r is unique hence our claim. If a does not divide b then $0 < r < a$. In that case none of the points in the arithmetic progression will be divisors of a . Therefore, r will be strictly greater than 0.

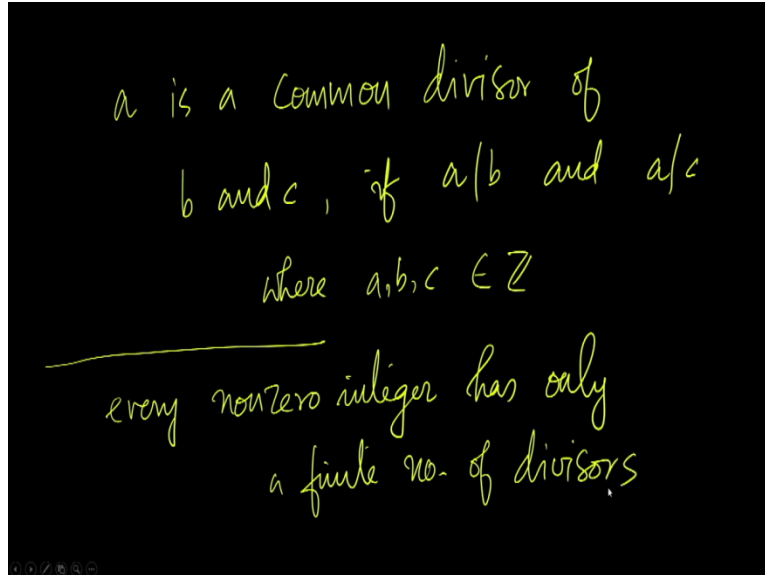

(Refer Slide Time: 18:09)

Now it is easy to show this theorem. For any two integers a and b where a is not equal to 0, there exist unique integers q and r such that b is qa plus r and $0 \leq r < |a|$.

See here we only say that a is not equal to 0 we do not assume that a is greater than or equal to 0.
So you can prove this theorem yourself.

(Refer Slide Time: 19:01)

We say that a is a common divisor of b and c if a divides b and a divides c where a, b, c are all integers. So a pair of numbers b and c can have multiple common divisors every nonzero integer has only a finite number of divisor.

(Refer Slide Time: 19:56)

Common divisors of $b, c \in \mathbb{Z}$
form a finite set.
greatest common divisor
is the largest.

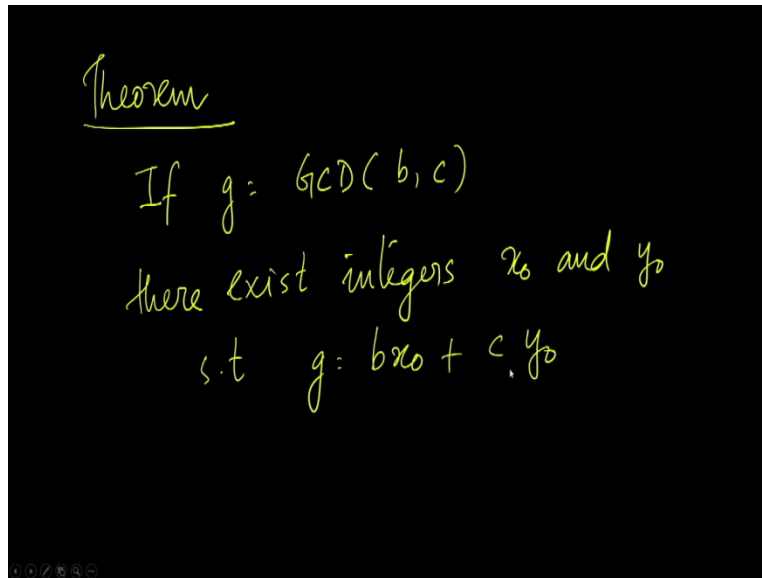

Therefore, the common divisors of two numbers b and c which are integers form a finite set. Therefore, we can talk about the greatest of them. The greatest common divisor happens to be the largest of this finite set.

(Refer Slide Time: 20:41)

$$\begin{aligned} \text{GCD}(b, c) & \text{ if } b \neq 0 \text{ or } c \neq 0 \\ \text{GCD}(b, c, d) & \\ & = \text{GCD}(\text{GCD}(b, c), d) \end{aligned}$$

So we will denote this by GCD of b and c if b not equal to 0 or c not equal to 0. We can extend this notion to multiple integers we can talk about GCD of b, c, d which is the GCD of GCD of b and c and d .

(Refer Slide Time: 21:16)

Now we shall study an interesting theorem which says that, If G is the GCD of two numbers b and c then there exist integers x and y such that G is $bx + cy$. In other words, if g is the GCD of b and c then g can be expressed as a linear combination of b and c with integer coefficients.

(Refer Slide Time: 22:03)

$b=3$ $c=7$ $\text{GCD}(3,7) = 1$

$1 \rightarrow 3x + 7y$

	x					
	-2	-1	0	1	2	
-2	-20	-17	-14	-11	-8	
-1	-13	-10	-7	-4	-1	$x = -2$
0	-6	-3	0	3	6	$y = 1$
1	1	4	7	10	13	$3x + 7y$
2	8	11	14	17	20	$= -6 + 7 = 1$

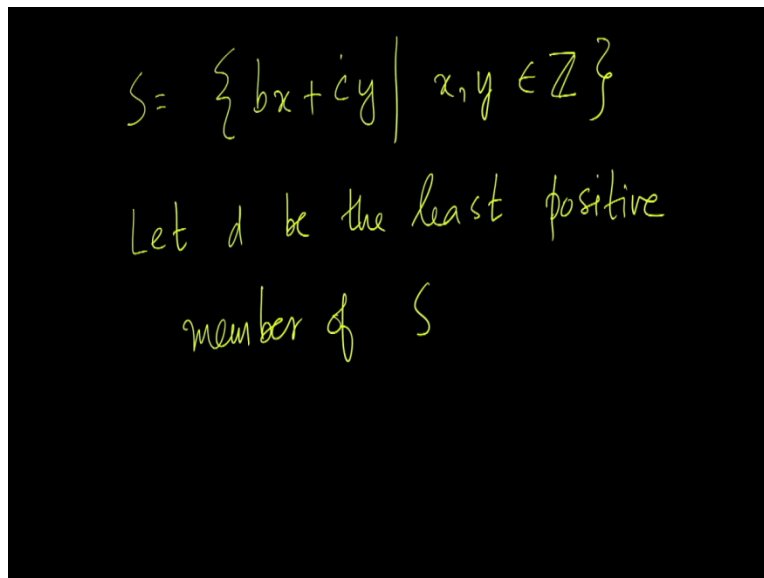

So let us see how to do this. In particular consider two numbers let us say b equal to 3 and c equal to 7. Then we want to express the GCD of these two which we know is 1. GCD of 3 and 7

is 1. We want to express 1 as a linear combination of -3 and 7. So we could write this as $3x$ plus $7y$ we have to find x and y so that 1 is equal to $3x$ plus $7y$ that is precisely what the theorem says, The GCD of two numbers can be expressed as a linear combination of those two numbers with integer coefficients x and y .

So let us consider the various possible values of x and various possible values of y . When x equal to 0, y equal to 0, we have the linear combination evaluating to 0. When x is 1 and y is 0 we have 3. When x is 2 y is 0 we have 6. On the negative side we have minus 3, minus 6. When y is 0 and x is 1 when x is 0 and y is 1 we have 7. when x is 0, y is 2 we have 14.

On the other direction we have minus 7 and minus 14. Here we have 10 and 17. This is how the values would look like. For various integral values of x and y , the linear combination $3x$ plus $7y$ would have these values. So you find that indeed there is one particular choice of x and y for which the linear combination of value is to 1. When x equal to minus 2 and y equal to 1 we have $3x$ plus $7y$ evaluating 2 minus 6 plus 7 which is 1. So there is a choice of x and y for which the linear combination evaluates to 1. So how do we generalize this? We want to bring the assertion for every pair of integers b and c .

(Refer Slide Time: 25:01)

$$S = \{ bx + cy \mid x, y \in \mathbb{Z} \}$$

Let d be the least positive member of S

So we have this pair of integers b and c . Let us define the set s as the set of all integers bx plus cy where x and y are integers. So it is precisely this set that we depicted here for integers 3 & 7. So

| this is clearly an infinite set. Let d be the least positive member of s . Depending on the various choices for x and y we have different values in s we are picking out the least positive member of s we call it d .

(Refer Slide Time: 25:57)

Say $d = bx_0 + cy_0$

If $d \nmid b$ then
there exist unique r, q s.t. $b = qd + r$
where $0 < r < d$

Say d is $bx_{\text{naught}\theta}$ plus $cy_{\text{naught}\theta}$. Every member of s is a linear combination of b and c for some choice of x and y . So d is also the same. So there is a choice of x and y namely $x_{\text{naught}\theta}$ and $y_{\text{naught}\theta}$ for which d is $bx_{\text{naught}\theta}$ plus $cy_{\text{naught}\theta}$. If d does not divide b , then there exist unique r and q such that b is qd plus r , where r is strictly between 0 and d .

(Refer Slide Time: 26:58)

$$\begin{aligned} r &= b - qd = b - q(bx_0 + cy_0) \\ &= b(1 - qx_0) + c(-qy_0) \end{aligned}$$

$0 < r < d$ $r \in S$
contradiction So $d|b$

So we have r is b minus qd which is b minus q into dx naught plus cy naught. Rearranging we get that, this is b into 1 minus qx naught minus c into qy naught or I can put plus here and move the negative sign here. So we have two integers 1 minus qx naught and minus into qy naught so that our is a linear combination of b and c with these as the coefficients.

But we know that r is strictly between 0 and d therefore what we have found is that r belongs to s and r is positive. But we had picked d as the least positive member of s and here we find r which is a positive is a member of s but is less than d . Therefore, we have a contradiction and from what we derived this contradiction we assume that d does not divide b and then got this contradiction therefore it must be that d divides b .

(Refer Slide Time: 28:28)

$$d|b, d|c$$

d is a common divisor of b & c

$$\text{Let } g = \text{GCD}(b, c)$$
$$d = bx_0 + cy_0 \rightarrow g|d$$

Similarly, we can also argue that d divides c . So if d divides b and d divides c then d is a common divisor of b and c . Now consider the GCD of b and c . Let g be the GCD of b and c . Since d is $bx_0 + cy_0$, we have that g divides d . g divides b and g divides c , so g divides $bx_0 + cy_0$ as per the theorem we saw earlier so g divides d .

(Refer Slide Time: 29:18)

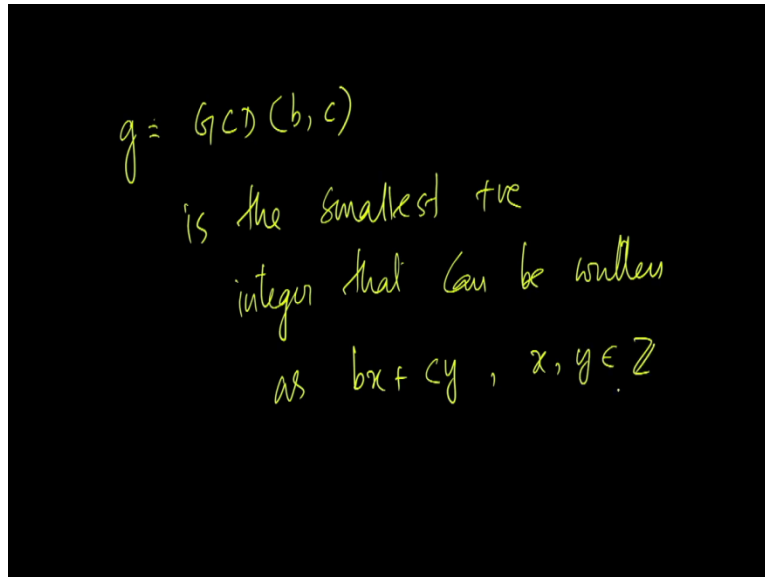

$$g \text{ and } d \text{ are +ve}$$
$$\text{so } \underline{g \leq d}$$

g is the GCD, d is a CD

$$\underline{g \geq d} \rightarrow \textcircled{g = d}$$

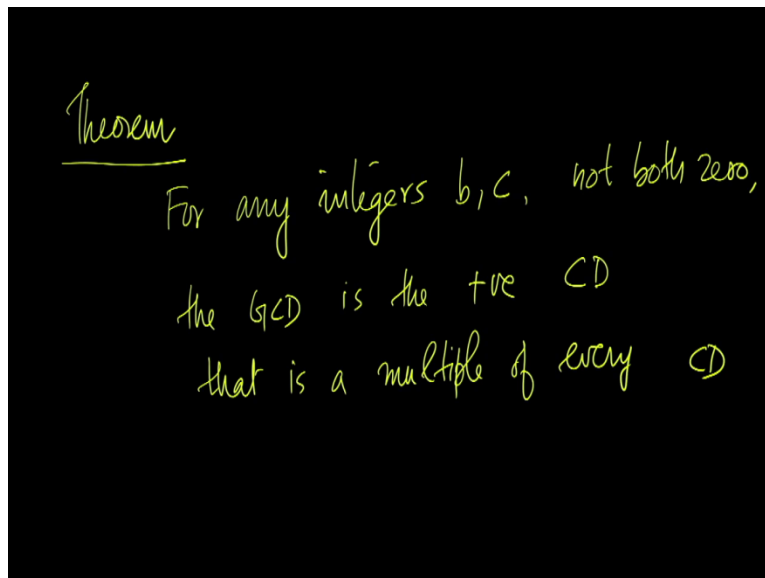

g and d are both positive. So since g divides d , g is less than or equal to d . But then g is the GCD of b and c and d is a CD a common device. g is the greatest common divisor therefore clearly g is greater than or equal to d in other words g is equal to d .

(Refer Slide Time: 30:01)

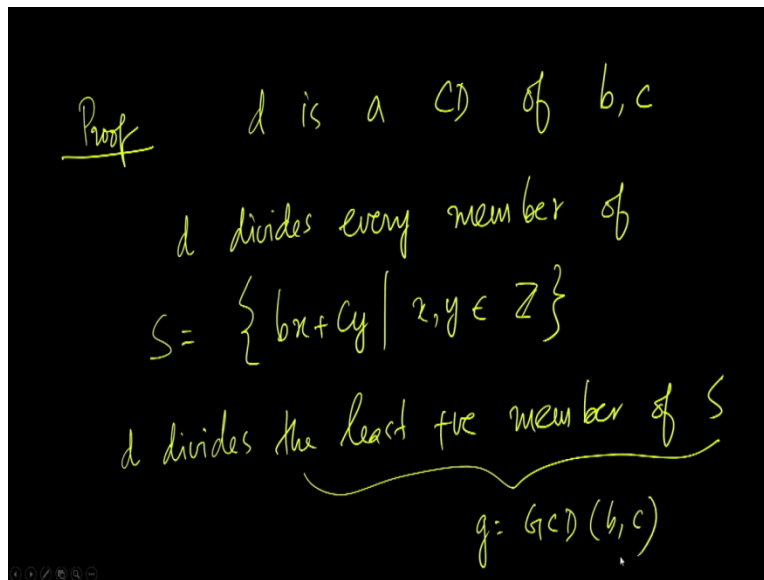

In other words, the GCD of b and c , this is the smallest positive integer that can be written as a linear combination of b and c with integer coefficients.

(Refer Slide Time: 30:37)

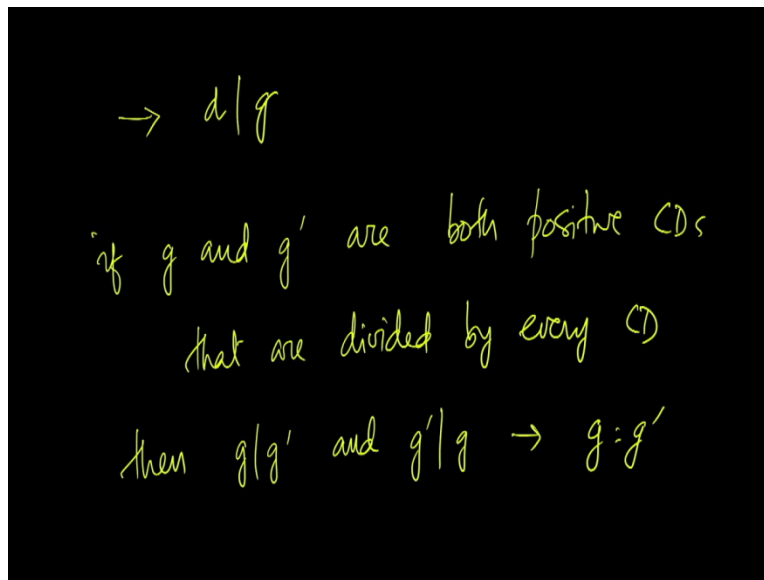

Now another theorem, For any two integers b and c not both 0. The GCD is the positive common divisor that is a multiple of every common divisor. For any pair of integers b and c , not both 0, the greatest common divisor happens to be the positive common divisor that is a multiple of every common divisor.

(Refer Slide Time: 31:33)

To prove this, suppose d is a common divisor of b and c , then d divides every linear combination of b and c . If d divides b and d divides c then d divides bx plus cy for any pair of integers x and y . So d divides every member of the set. In particular d divides the least positive member of the set. This is what we call g . But then what is the least positive member of S . That happens to be the GCD b and c so if d is a common divisor of b and c then d divides g .

(Refer Slide Time: 32:45)

So every common divisor of b and c divides g . If g and g' are both positive common divisors, that are divided by every common divisor, then g and g' are themselves common divisors then we have g divides g' and g' divides g , which implies g equal to g' .

But in other words g is the only common divisor with this property the only common divisor that is divided by every common divisor of b and c . In other words, the only common divisor of b and c which is divided by every common divisor of b and c is the GCD of b and c .

(Refer Slide Time: 33:58)

Theorem
For every positive integer d ,

$$\text{GCD}(bd, cd) = \text{GCD}(b, c) \times d$$

$\text{GCD}(bd, cd) =$ the LCM of $\{bdx + cdy \mid x, y \in \mathbb{Z}\}$
which is $d \times$ the LCM $\{bx + cy \mid x, y \in \mathbb{Z}\}$
 $d \times \text{gcd}(b, c)$

Another theorem regarding GCD's for every positive integer d we have that GCD of bd, cd equals GCD of bc multiplied by d . What is the GCD of bd and cd . This happens to be the least positive member of the set $bdx + cdy$ where x and y are integers. Which is d times the least positive member of $bx + cy$, where x and y are integers.

This is the case when d is a positive integer which is indeed the case here. But this is the GCD of b and c that is precisely what we wanted to show. So you can remove common factors from bd and cd . d is a common factor of bd and cd and then find the common GCD of the remnants.

(Refer Slide Time: 35:48)

Theorem For every positive d
 d of b and c

$$\text{GCD} \left(\frac{b}{d}, \frac{c}{d} \right) = \frac{\text{GCD}(b, c)}{d}$$

$$d \leftarrow d \quad b \leftarrow \frac{b}{d} \quad c \leftarrow \frac{c}{d}$$

Now the related theorem is this, for every positive common divisor d of b and c GCD of b by d , c by d is GCD of b and c divided by d . How do we prove this? In the previous theorem you put b by bd , c by cd and d by d . If you substitute thus in this theorem we get the new theorem as a corollary.

(Refer Slide Time: 36:48)

Theorem

If $\text{GCD}(a, d) = 1$
 $\text{GCD}(b, d) = 1$

then $\text{GCD}(ab, d) = 1$

$$\left(\frac{a}{d} \right) \quad \left(\frac{b}{d} \right) \quad \left(\frac{ab}{d} \right)$$

Yet another theorem if GCD of a and d is 1 and GCD of b and d is 1 then GCD of ab and d is 1. In other words, look at the fraction $\frac{a}{d}$ you cannot reduce this fraction anymore a and d do not cancel. Similarly, b and d also do not cancel. B and d do not have common factors other than 1 therefore if you consider $\frac{ab}{d}$ then d cannot cancel against ab.

d and $\frac{a}{d}$ do not have common factors d and b do not have common factors other than 1 therefore d and ab also will not have common factors other than 1. Of course intuitively clear to you but how do you prove it?

(Refer Slide Time: 37:57)

Proof $\text{GCD}(a, d) = 1$
 $\text{GCD}(b, d) = 1$

$$\left. \begin{aligned} 1 &= ax_0 + dy_0 \\ 1 &= bx_1 + dy_1 \end{aligned} \right\} \begin{aligned} \exists x_0, y_0 \\ x_1, y_1 \in \mathbb{Z} \end{aligned}$$

We know that GCD of a, d equal to 1 GCD of b and d is also equal to 1. Therefore we have integers x_0, y_0, x_1, y_1 so that 1 is $ax_0 + dy_0$ plus $bx_1 + dy_1$. So there exists x_0, y_0, x_1, y_1 all integers. So that this is satisfied.

(Refer Slide Time: 38:52)

$$\begin{aligned} z_1 &= dy_0 y_1 - y_0 - y_1 \\ z_0 &= x_0 x_1 \\ \hline ab(z_0) &= (1 - dy_0)(1 - dy_1) \\ &= 1 + dz_1 \end{aligned} \quad \text{GCD}(ab, d) = 1$$

$$ab(z_0) + d(-z_1) = 1$$

Let us define z_1 as $dy_0 y_1 - y_0 - y_1$ and z_0 as $x_0 x_1$. If this is the case, then we readily find that $ab(z_0)$ is $1 - dy_0 - dy_1 + dz_1$. Replacing x_0 and x_1 with $1 - dy_0$ and $1 - dy_1$ we find that $ab(z_0)$ is this. Which is $1 + dz_1$. That is $ab(z_0) + d(-z_1)$ equal to 1.

Therefore if you consider the linear combinations of ab and d with integer-, the least positive member of that set is going to be 1. If 1 is present in that set, certainly 1 has to be the least among them. In other words, GCD of ab and d will have to be 1. That is it from this lecture. We will see more properties of GCD in the next class hope to see you in the next. Thank you.
