Recursive State Estimation

- ▶ **State** $(x_0, x_1, x_2, \dots, x_t)$:
 - Robot Pose / location in world
 - Configuration of Actuators
 - Surrounding object locations
 - location and velocity of other moving objects
 - Internal mechanics (Battery life, etc.)
 - etc.

Complete states: We consider a state representation 'complete' if the future is independent of the history $\{(x_0, \dots, x_{t-1}), (u_1, \dots, u_{t-1}), (z_1, \dots, z_{t-1})\}$ given the present state x_t . (Markov property)

Introduction to Robotics Prof. Balaraman Ravindran

Last lecture, we were looking at state estimation, we started talking about Recursive State Estimation. And so, we were talking about what constitutes a state. The state at each time t , could be a very complicated vector of various entities that you could record, like the robot pose, the location of the world. This could be the xyz location, and also the orientation theta.

And the velocity with which, if it is a mobile robot, the velocity with which it is moving, and so on, so forth. And then the configuration of actuators, so in what angles are the arms in the gripper is in, and whether it is holding an object, and so on, so forth, and locations of surrounding objects, etc, etc. So, we said that this could be potentially a very complex state.

(Refer Slide Time: 01:05)

► Interaction

Measurement Data (z_1, z_2, \dots, z_t)

- Camera image
- Ultrasonic sensor output
- etc.

Control Actions (u_1, u_2, \dots, u_t)

- Robot motion
- Manipulation of objects
- etc.

We Assume $x_0 + u_1 \rightarrow z_1$

Notation:

$x_{0:t} : x_0, x_1, \dots, x_t$

$u_{1:t} : u_1, u_2, \dots, u_t$

$z_{1:t} : z_1, z_2, \dots, z_t$

And then we started talking about measurement data. This is essentially what the sensors give you and likewise, we had z_1 to z_t . So, this measurement data could be camera images, could be ultrasound sensor data, and could be other kinds of touch sensors and internal indicators, like battery levels, and so on, so forth. And then finally, you have a set of control actions, which could be movement actions, it could be manipulation actions, and sometimes it could just be sensory actions, like turn on a camera or rotate a camera in a certain direction, so that you get a different kind of input.

And so, we also adopted this notation that you start in state x_0 , you perform action u_1 , and you end up at x_1 that were you take measurement z_1 . And so likewise, throughout, you are at x_{t-1} , you do u_t , you end up at x_t when you make a measurement z_t . So that is the way we are going to be looking at it. And the notations are as follows. So, when I want to denote a entire sequence x_0 to x_t , I will use $x_{0:t}$, just remember that. Likewise, $u_{1:t}$ and $z_{1:t}$, to denote the entire sequence, it could start from anywhere and could go to anywhere. It could start from $t-1$ and go to $t+1$ also. So that does not matter.

(Refer Slide Time: 02:34)

Probabilistic Robotics - Sebastian Thrun, Wolfram Burgard, and Dieter Fox. MIT Press. 2005.

So, in the last lecture, I mentioned that we will be using this textbook, I just wanted to make sure that everyone has gotten down. So, we will be using the textbook on Probabilistic Robotics, by Sebastian Thrun from Burgard and Dieter Fox, it is from MIT Press and there are draft versions of the textbooks also available freely online. This is not the complete version of the book, but as a reference, you could use these draft versions. And the book is very extensive and like I said, we will not be covering all parts of the book, only some of the highlights from the book.

(Refer Slide Time: 03:10)

The dynamical stochastic system of the robot and its environment are described by *state transition probabilities* and the *measurement probabilities*.

► **State Transition probability:**

$$p(x_t | x_{0:t-1}, u_{1:t}, z_{1:t-1})$$

Assuming the Markov property,

$$= p(x_t | x_{t-1}, u_t)$$

► **Measurement probability:**

$$p(z_t | x_{0:t}, u_{1:t}, z_{1:t-1})$$

Assuming the Markov property,

$$= p(z_t | x_t)$$

And what we then started talking about is the system model. And I said the system model consists of two quantities, one is the state transition probability, the first one is the state transition probability. The first one, so the it consists of two quantities, the first one is the

state transition probability, where you look at the probability that you land up in a certain state x_t , for example, probability that I land up in front of open door, given that I have been in the past sequence of states given by x_0 to x_{t-1} and that I have taken the actions given by u_1 to u_t and I have made observations z_1 to $t-1$.

And then we assume that the Markov property holds and therefore we can write this as p of x_t given x_{t-1} and u_t . And the next quantity we look at is what we call the measurement probability, which is assuming that under the Markov property, the measurement probability is just assuming that I have, I am in state x_t , what is the probability that I will make a measurement z_t . So, we are looking at probability that I will be making a certain measurement z_t at time t , given the history of states that I have visited up till time t .

And the actions have taken up to time t and the observations I have made until time $t-1$, and all of this put together or the factors that my current observation could depend on. And if you are assuming the Markov property, the observation depends only on the current state x_t . And we also talked about how z_t does not figure in the state transition probability, because z_t does not cause x_t , z_t is caused by x_t that is actually captured in the measurement probability.

Now, assuming that you did not have this noise, assume that the world is clearly observable. Assume that all you need to know, let us say you have a wheeled robot that is moving around in a 2d workspace, all you need to know is the exact x and y coordinate of the robot. And that is all the information that you need to make all the decisions you need in the world. In such a scenario, let us say, if I make a measurement, I know exactly where I am. So, I know my state because the measurement is going to be like something like a GPS signal, that gives me the xy lat long, very accurately.

So, at every point, I will know what state I am in. So, if I tell you that you have made a measurement that tells you your lat long is x and y , then I know that I am in location x, y , then I make a movement, I say I move north and then I make another measurement. Now this measurement again gives me my lat long x and y , and therefore, I know exactly where I am. But the entire complication, the whole reason that we are looking at recursive state estimation right now is that I do not have such noise free measurement and I also have a problem with my modeling, motion modeling.

But right now, we are only looking at the fact that my measurements are not noise free, and they are noisy. And therefore, I cannot exactly tell you what state I am in, the robot is not

able to decide what state the robot is in, and therefore has to, so the robot is not able to exactly measure the state it is in, and therefore has to look at a probabilistic estimate.

(Refer Slide Time: 07:05)

Recursive State Estimation

Belief: As discussed, typically, state cannot be measured directly. A *Belief* reflects the robot's internal knowledge about the state of the environment.

Belief Distributions: A belief distribution assigns a probability to each possible state variable, conditioned on the available data.

$$bel(x_t) = p(x_t | z_{1:t}, u_{1:t})$$

Occasionally, it will prove useful to calculate a posterior before incorporating z_t , just after executing the control u_t

$$\bar{bel}(x_t) = p(x_t | z_{1:t-1}, u_{1:t})$$

We call this value the '*prediction*' as it does not incorporate the current measurement z_t .

- Calculating $bel(x_t)$ from $\bar{bel}(x_t)$ is called *correction* or the *measurement update*.

Introduction to Robotics Prof. Balaram Ravindran

So, we call this estimate of the robot, the robot is essentially trying to, you know decide what state it is in. At any point of time, this internal confusion about the actual state the robot is in, is captured in what we call as a belief. The belief is essentially reflects the robots internal knowledge or internal confusion, if you would be the flip side of it, is about the state in which it is in. So, for example, if the robot could be in one of two places, it could be in room 1, or it could be out of room 1, let us say these are the two things the robot could be.

And then when it makes a measurement and the measurement just tells it, you are near a door, that does not really let you know, whether you are inside room 1, or whether you are outside room 1, it could be near the door in any way. And then the only way that you could be sure about where you are is actually take some actions and see what happens with regard to the effects of actions, and then continuously refine your belief. So, when I start off with no knowledge of where I am, I could say that there is a half chance that you are inside the room and a half chance you are outside the room.

So, this kind of a probabilistic distribution over possible states is called as a belief. And sometimes we use belief, sometimes we use belief distribution. So formally, a belief distribution assigns a probability to each possible state variable and conditioned on everything that you know so far. So formally, I would say that belief x_t , so belief x_t would

be, belief x_t would be the belief that you have that, what is the state that you are in at time t . So, x_t is remember, x_t is a variable that tells you what state you are in time t .

So, it could be in multiple states. So, it is actually given by a probability of you occupying a specific state x_t , given the entire history of observations that you have made, and the entire history of actions that you have taken. So, remember that you never get access to your actual state. Sometimes you can assume that you know x_{naught} , that is the state that you start in, but even that is not available to you often. So, you basically only have a sequence of actions that you took, and the sequence of observations you made, that is all that the robot knows for sure.

And so, given the sequence of actions and observations, what is the probability that I am in a particular state at time t , so that is essentially the belief at t . So, for every possible value that x_t can take, you will have one probability, and that basically is your probability distribution at time x , at time t . So, this essentially, is a quantity that we call as a belief, and we will denote it by $\text{bel } x_t$. I think I know that it is a little confusing right now, it will become clearer when we look at an example later.

And just keep in mind that when I say belief x_t , it does not really mean that the robot is actually in two different states with some probability. The robot is always in one state, this robot is not a quantum robot, that it can be in multiple states at the same time, robot is always in one state, just that it does not know what the state is. So, the belief does not encode the actual position of the robot, the belief represents the robot's estimate on the position.

So, believe tells you what the robot thinks is the position, not what the actual position of the robot is. The actual position of the robot is some x in the world that you do not know yet. So and the belief tells you, what is that robot's estimate of where it is in the state space. So, while we are trying to compute the belief, it might sometimes be useful for us to compute a quantity, which we will denote as bel bar , which is a prediction of where it expects to be after it does an action.

So, the $\text{bel bar } x_t$ is essentially the probability of x_t , given z_1 to t minus 1, and u_1 to u_t . So, the difference between bel and bel bar is that bel is conditioned on z_1 to t and u_1 to t , where bel bar is conditioned on z_1 to t minus 1 and u_1 to t , it needs to know the last action that you performed also. So now you might actually start thinking a little bit about, hey what happened to all this Markov properties week are talking about, why are we talking about the

belief, now conditioning it on the entire history of observation, the entire history of states in the entire history of actions, and so on, so forth.

The reason that we have to condition on the history of observations and history of actions is because we do not know the state. If I know x_{t-1} , then I can make this more Markov. If you know x_{t-1} , then it depends only on x_{t-1} and u_t . Since I do not know x_{t-1} , I have to look at the entire history of observations and the entire history of actions I have performed in order to define my belief.

And note again, the dynamics, the underlying dynamics of the robot problem is still Markov, we are not changing that, the underlying dynamic system Markov but because I do not have access to the true state, my belief estimations would be dependent on the complete history. So, you should remember that. So, just because I put the whole history here does not mean that the problem has become non Markov, is it clear. So now, so we have this quantity \bar{b}_t , which say is the prediction.

So why I say it is a prediction, I have not yet made a measurement of where I actually landed up. So, I have data for all the past measurements I have made, z_1 to z_{t-1} . And I have data of all the actions I have taken, including the current action. So, after I have taken the current action, I am going to say, hey, where should I go, I should be, you know, maybe I am trying to leave the room. So, with some probability, you know 80 percent I will leave the room. So, I would say that, hey, if I was in the room earlier, now I have left the room. And that is what I should be looking at. So, I am no longer inside the room.

And this prediction, as you see on the slide does not incorporate the current measurements z_t . So, if you notice the difference between \bar{b}_t and b_t was that measurement z_t . So, going from \bar{b}_t to b_t , so calculating b_t from \bar{b}_t is actually called the measurement update, or sometimes called the correction update. So, whenever I go from my, whenever I compute \bar{b}_t , I am saying that I make a prediction, so we will we will make this more clear in the next few slides. Whenever I compute \bar{b}_t , I am making a correction, I am making a prediction.

And when I compute b_t from \bar{b}_t , I am making a measurement update or a correction update. So sometimes \bar{b}_t is called the prediction or a movement update or motion update, or the transition update. And going from \bar{b}_t to b_t is the measurement update. So, we saw these two quantities earlier.

(Refer Slide Time: 15:24)

Recursive State Estimation

The Bayes Filter Algorithm

- ▶ This algorithm calculates the belief distribution from measurement and control data, recursively calculating $bel(x_t)$ from $bel(x_{t-1})$.
- ▶ There are two steps to this algorithm: *prediction* and *measurement update*.

Introduction to Robotics Prof. Balaraman Ravindran

So let us, let us move on, so let us move on. So, we will now look at the base filter algorithm. So, we will now look at the base filter algorithm. And the idea behind the base filter algorithm is to recursively update your belief. So, the idea here is that I am going to compute belief of x_t , that is, that is the belief at time t . So, what is my distribution over the value that the state can take at time t , I am going to compute that from not only the dynamics, I know the motion model, and I know the measurement model.

We assume that I have the motion model, I have the measurement model and I also have access to the observations and the actions. So, what do I have, I have the motion model that we talked about, the transition model that we talked about, I have the measurement model, I have access to all the observations I have made so far, and I have access to all the actions I have taken so far. Given that I have all of these, how do I take belief x_t minus 1. So, what is belief x_t minus 1 the distribution of states at time t minus 1.

How can I take that and use that to compute belief x_t . So, and as you could guess there are two steps to this algorithm. So, we have the prediction step where we compute \bar{bel} of x_t from bel x_t minus 1, and the measurement step that we compute bel , x_t from \bar{bel} x_t , is that clear, so let us move on.

(Refer Slide Time: 17:03)

Prediction:

$$\bar{bel}(x_t) = p(x_t | z_{1:t-1}, u_{1:t})$$

$$p(x|z) = \int p(x|y,z)p(y|z)dy$$

$$\text{Using } p(x) = \int p(x|y)p(y)dy$$

$$= \int p(x_t | x_{t-1}, z_{1:t-1}, u_{1:t}) p(x_{t-1} | z_{1:t-1}, u_{1:t-1}) dx_{t-1}$$

Assuming Markov Property,

$$= \int p(x_t | x_{t-1}, u_t) p(x_{t-1} | z_{1:t-1}, u_{1:t-1}) dx_{t-1}$$

$$= \int p(x_t | x_{t-1}, u_t) \bar{bel}(x_{t-1}) dx_{t-1}$$

So, let us look a little bit more detail at the prediction problem. So, what is a prediction problem. Remember, a prediction problem is compute $\bar{bel}(x_t)$ as a probability of x_t , given z_1 to t minus 1, and u_1 to t . Now, we know that from identities of probability, we know that p of x is equal to integral p of x given y , $p(y) dy$. Now, I am going to use this in order to simplify this expression, and somehow introduce $\bar{bel}(x_{t-1})$. So, to simplify this expression, so I am going to do this integral over all possible values that x_{t-1} would take.

Just to recall, so what this integration does, it is essentially runs over the entire gamut of values that y can take and look at for every value that y can take, what is the distribution over x . And then multiply that with the probability that y can take that value, and do this for the entire range of values that y can take. So, this integral would give, allow me to condition x on y and give me what is p of x . So likewise, now, I going to take this expression, so I want p of x given z and u , so I am going to condition it on x_{t-1} .

So now we have a probability of x given y this integral, property x even y into property y . But suppose I want to do probability of x given z . Now, I can write that as integral of probability of x given y comma z times probability of y given z dy . And so of course, I had to take the integral over here, I can take the integral of that, and that gives me the expression that I want. So that is exactly what we are doing here now. And once now that I want probability of x given z comma u , I am going to do probability of x_t given x_{t-1} , z_1 to t minus 1 u_1 to t times probability of x_{t-1} given z_1 to t minus 1, u_1 to t minus 1 dx_{t-1} .

So, if I assume that we actually have the Markov property, so some of these things can get simplified. So how do I simplify with the Markov property, notice that I said the Markov property applies whenever I know x_{t-1} , if I do not know x_{t-1} I have to condition on the entire history. But if I know x_{t-1} , I can get away with throwing away the history. So, since I have x_{t-1} here, I can throw away the history.

And then I can simplify that to probability of x_t given x_{t-1} . I still need u_t because u_t comes after x_{t-1} . So, I need x_{t-1} and u_t , that gives me this the first expression using the Markov property. The second expression stays the same, it is probability of x_{t-1} given z_1 to $t-1$, u_1 to $t-1$, x_{t-1} . But then if you think about it, what is this expression probability of x_{t-1} given z_1 to $t-1$ and u_1 to $t-1$.

(Refer Slide Time: 20:52)

Recursive State Estimation

Belief: As discussed, typically, state cannot be measured directly. A *Belief* reflects the robot's internal knowledge about the state of the environment.

Belief Distributions: A belief distribution assigns a probability to each possible state variable, conditioned on the available data.

$bel(x_t) = p(x_t | z_{1:t}, u_{1:t})$

Occasionally, it will prove useful to calculate a posterior before incorporating z_t , just after executing the control u_t

$\overline{bel}(x_t) = p(x_t | z_{1:t-1}, u_{1:t})$

We call this value the '*prediction*' as it does not incorporate the current measurement z_t .

- Calculating $bel(x_t)$ from $\overline{bel}(x_t)$ is called *correction* or the *measurement update*.

Introduction to Robotics
Prof. Balaraman Ravindran

If you think about it, that is exactly what our belief expression was, belief x_t is probability of x_t given z_1 to t , u_1 to t . Now belief x_{t-1} would be probability of x_{t-1} given z_1 to $t-1$, u_1 to $t-1$.

(Refer Slide Time: 21:08)

Prediction:

$$\bar{bel}(x_t) = p(x_t | z_{1:t-1}, u_{1:t}) \quad p(x|z) = \int p(x|y,z)p(y|z)dy$$

$$\text{Using } p(x) = \int p(x|y)p(y)dy$$

$$= \int p(x_t | x_{t-1}, z_{1:t-1}, u_{1:t}) p(x_{t-1} | z_{1:t-1}, u_{1:t-1}) dx_{t-1}$$

Assuming Markov Property,

$$= \int p(x_t | x_{t-1}, u_t) p(x_{t-1} | z_{1:t-1}, u_{1:t-1}) dx_{t-1}$$

$$= \int p(x_t | x_{t-1}, u_t) \bar{bel}(x_{t-1}) dx_{t-1}$$

Motion model

..

So that is a, so that is essentially our belief expression. So, I can, I can replace this with belief x_t minus 1. So now my \bar{bel} expression has now become something very simple. My $\bar{bel} x_t$ equal to integral probability of x_t given x_t minus 1 comma u_t . So, this is essentially my motion model, that is essentially my, so that is my motion model, so that is my motion model. And then I have my belief x_t minus 1, dx_t minus 1. So, my \bar{bel} is essentially integral of the motion model times the previous belief, taken over all values that for the previous state. So that is basically it.

(Refer Slide Time: 22:10)

Measurement Update:

$$bel(x_t) = p(x_t | z_{1:t}, u_{1:t}) \quad p(x_t | z_{1:t-1}, z_t, u_{1:t})$$

$$\text{Using Bayes rule } \{p(A|B) = \frac{p(B|A)p(A)}{p(B)}\},$$

$$= \frac{p(z_t | x_t, z_{1:t-1}, u_{1:t}) p(x_t | z_{1:t-1}, u_{1:t})}{p(z_t | z_{1:t-1}, u_{1:t})}$$

$$= \eta p(z_t | x_t, z_{1:t-1}, u_{1:t}) p(x_t | z_{1:t-1}, u_{1:t})$$

Assuming Markov Property,

$$= \eta p(z_t | x_t) p(x_t | z_{1:t-1}, u_{1:t}) = \eta p(z_t | x_t) \bar{bel}(x_t)$$

Measurement Model

So now, once I have \bar{bel} , now next thing would be to do the measurement update. So here in the measurement update, I go from \bar{bel} , go from \bar{bel} to bel . So, let us look at the bel definition again. So, $bel x_t$ is p of x_t given z_1 to t , u_1 to t . So that is essentially what $bel x_t$ is.

Now I am going to use the Bayes rule, all of you are familiar with the Bayes rule, probability of A given B equal probability of B given A times probability of A divided by probability of B, I am pretty sure all of you are familiar with this rule.

Now, using that I am going to rewrite this. So, if you think of z_1 to t , z_1 to t is actually z_1 to t minus 1 comma z_t , so I am going to bring that out here. So now I am going to look at probability of z_t , given x_t comma z_1 to t minus 1, u_1 to t times probability of x_t , given z_1 to t minus 1, this is essentially in p of A part. So, I have, this is my p of B given A, this is my p of A, which is probably of x_t , given all the previous measurements, and all the actions I have taken so far, and divided by probability of B part, which is probability of z_t , given z_1 to t minus 1 u_1 to t .

So, this is essentially applying Bayes rule here assuming that I am looking at probability of x_t , given z_1 to t minus 1 comma z_t comma u_1 to t . So, this is assuming that, that is my expression, as supposed to x_t z_1 to t . I am just splitting up z_1 to t as z_1 to t minus 1, z_t and u_1 to t , so I am assuming that my z_t is my B and my x_t is A and the rest of the variables are all conditioning variables. So therefore, I use the, I apply Bayes theorem and write it as probability of z_t given x_t , z_1 to t minus 1, u_1 to t times probability of x_t given z_1 to t minus 1 u_1 to t divided by probability of B.

Now, if you think about it, I can again apply the Markov property because my x_t has now gone to the conditioning part. I am assuming that I am, what is the, I am asking the question, what is the probability of z_t , given x_t . As soon as I ask that question, I can assume the Markov property. And I can simplify the first term in the expression as probability of z_t , given x_t , I do not have to worry about the history after that. So, this is what we said in the measurement model.

So, this guy is essentially my measurement model. And what about the rest of it, it is a probability of x_t , given z_1 to t minus 1 and u_1 to t , and that is exactly my bel bar. So, this is my bel bar update, that is my bel bar function. So, I have it, I have my measurement model into my bel bar of x_t . And the denominator actually does not depend on x itself and I can just replace it with some kind of a normalizing factor η , which essentially, I could just sum the numerator for all possible values. And then normalize it so that I get a probability distribution.

I compute this P of bel of x_t , you can think of some kind of temporary variable, for every possible value that x_t can take, I compute the numerator, and then I divide all of these by the sum of all the numerators I computed and that gives me the probability. So that is where the η is, it is some kind of a normalizing factor. And I mean, technically η is supposed to be probability of z_t given z_1 to t minus 1, u_1 to t but it is a little hard to compute. And therefore, we just use this normalization trick.

So instead of actually computing the transition on the observations alone, without worrying about the states, I use known quantities, what are the known quantities I am using, I am using the measurement model. Let us go back. So, I am using the, so I am using the measurement model, and I am using bel bar, which we just computed on the previous slide using known quantities again. So, using both the measurement model and bel bar, we are able to compute what is belief without ever computing the denominator.

So, we just compute the numerators, and then normalize across all the possible values that x_t could take. Now if x_t could take continuous values, then normalization becomes a little tricky. And so, what we will see in the next few lectures are techniques for making this computation tractable, by making assumptions about the form of the transition function, the motion model, the form of the measurement model, and also the representation for the belief.

Right now, I have made no assumptions I am making, I am just telling you, these are very general probability distributions. As we go along, so we will start making specific assumptions about the transition model, we will start making specific assumptions about the measurement model and about the belief so that we come up with different kinds of tractable computations. Right now, η is easy for you to compute, if you think that x_t can take only a small number of finite values, small number of values.

But if x_t can be like a continuous value output, so like orientation, you could just take any value or it could be velocity or even x y coordinates, like it could be anywhere in the workspace, then computing this η , basically having to compute over all possible values for the belief is going to be a little tricky and we need to have some assumptions about how the belief looks like, so that I can do the computation tractably.
