**Small Signal Stability of a Single Machine Infinite Bus System**

Friends, today we start with the study of small signal stability. We shall devote our discussion towards the small signal stability of a single machine infinite bus system that is for understanding the concepts related to the small signal stability, we will consider a simple system and that is a single machine connected to an infinite bus. Okay the small signal stability is the ability of the system to maintain synchronism under small perturbations. The small perturbations continuously occur in any power system due to changes in loads and generations.

Now for analyzing the small signal stability of any system, the system model can be linearized around an operating point that is the disturbances are considered to be so small or incremental in nature. So that we can develop a linear model of the system around the operating point, once we develop the linear model of the system we can understand the behaviour of the system under small perturbations, various parameters of the system which affect the stability of the system further the moment we have a linear model we can apply the linear control system theory for designing the controllers.

Now here when I talk about the controller particularly we are interested in designing the excitation system control that is the voltage regulator and the power system stabilizers as we will see that in any power system right, the actual system is some what complex it is not as simple as a machine connected to infinite bus is always a multi machine system right. Now in any multi machine system as you know that the system will have different modes of oscillations, the modes of oscillations are classified as local modes of oscillations, inter area modes of oscillations and the control modes okay.

Now, primary requirement of the system is that this system should have for stability this will have positive synchronizing torque coefficient and positive damping torque coefficient. The stability of the system will be affected if any of these two torques or any of these two torque coefficients become negative. Okay now to start with we will study first a simple model considering constant flux linkages in the field winding that is we will first start with the constant flux linkage model, next we will include the the field winding dynamics that is we will consider next step the constant field voltage and must we assume these voltages applied to the field winding as a constant okay we the model is developed so that we take care of the the dynamics of the field winding that is changes in the field flux linkages.

This particular stage when we say that the applied voltage is fixed means it is a practically a manual control after studying this model with constant field voltage, we will extend it to the model which will include the automatic voltage regulator and we will study the affect of the

parameters of the excitation system and gain setting of the automatic voltage regulator on the stability of the system. Then the next step will be we include auxiliary controllers that is the power system stabilizer that is this the stage by step development will give us the complete insight into the small signal stability problem.

(Refer Slide Time: 06:52)

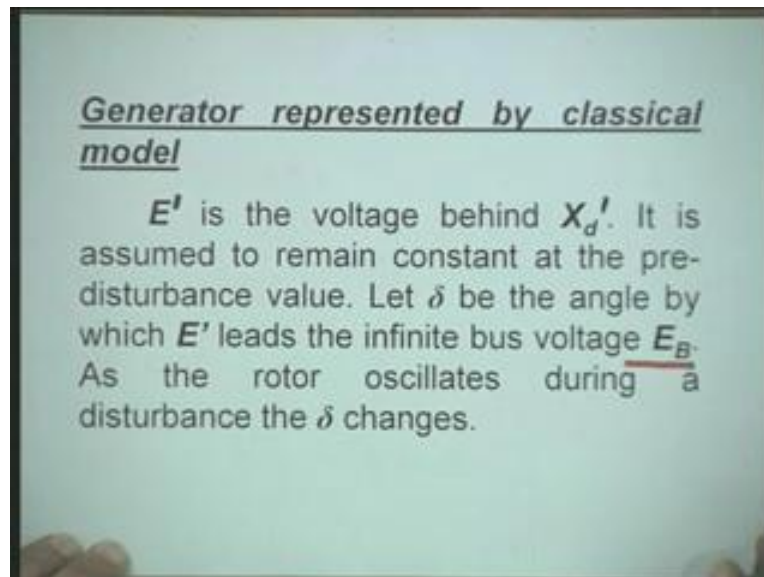

The system which we consider for small signal stability to start with is a machine infinite bus system where a synchronous generator is connected to a large system which can be characterized by a infinite bus, the equivalent circuit can be represented as generator the we represent the terminal voltage of the generator, the line is represented by an equivalent impedance  $Z$  equivalent equal to  $R_E$  plus  $j$  times  $X_E$  and connected to an infinite bus right.

Now here here even in a multi machine system, multi machine system right. Now if you if you take out one generator and the connected line right then just will be system if you represent by a infinite bus then it becomes a machine infinite bus system. Now as we continue our studies to simplify our model and understanding the resistance of the line or the equivalent resistance  $R_E$  we may may be ignored.

Now when we consider a classical model that is we assume the field flux linkage is to be constant. Okay now when we consider the classical model of the synchronous generator then the classic the synchronous generator is represented by a constant voltage behind direct axis transient reactance right. Now here we will represent the voltage behind transient reactance by the symbol  $E'$  and the voltage of the infinite bus as  $E_B$ , okay and the phase angle, phase angle between  $E'$  and  $E_B$  is denoted by  $\delta$  right and that is the power angle of the system.

(Refer Slide Time: 08:21)

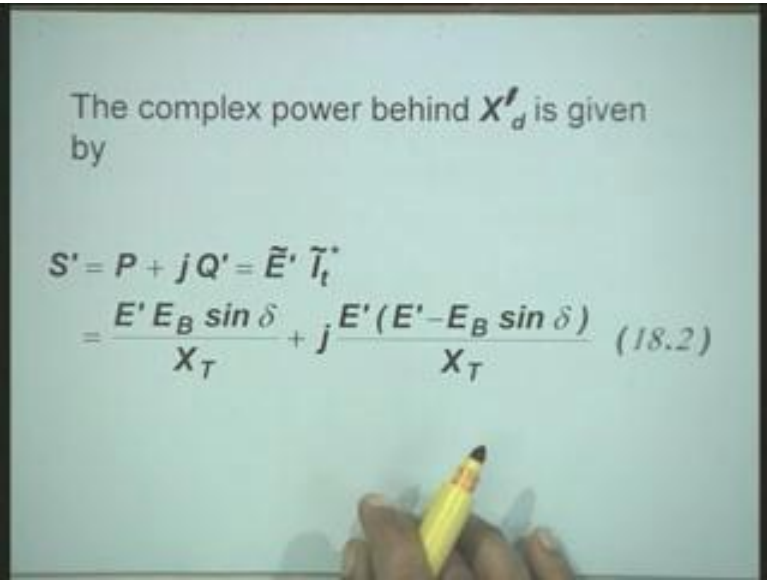

(Refer Slide Time: 09:15)

$$\begin{aligned}\tilde{I}_t &= \frac{E' \angle 0 - E_B \angle (-\delta)}{jX_T} \\ &= \frac{E' - E_B(\cos \delta - j \sin \delta)}{jX_T} \quad (18.1) \\ \tilde{E}' &= \tilde{E}_{t0} + jX_d' \tilde{I}_{t0} \\ X_T &= X_d' + X_E\end{aligned}$$

Now for this machine infinite bus system we have derived earlier the the power angle characteristic okay the power angle characteristic to derive we can start with the the terminal current of the synchronous generator as the  $E'$  minus  $E_B$ . Now here we are representing the the voltage behind transient reactance if it is represented as the as  $E'$  angle 0 that is you you consider this as a reference voltage generally we do other way around we consider the infinite bus voltage as reference and the internal voltage leads the reference voltage by some angle  $\delta$  okay but it does not matter very much.

We can write down the expression for current  $I_t$  this is the first step for solving this problem by this what we know will be the the you know whenever we start solving the problem the terminal voltage of the machine will be known to us right and therefore, once the terminal voltage is known we can find out the internal voltage by this formula  $E' = E_t + j X_d' I_t$ , where here now we denote this total reactance  $X_d, X_T$  as  $X_d'$  plus  $X_E$  earlier the power angle characteristic which we derived was relating the terminal voltage with the internal voltage but now here we will be deriving the power angle characteristic relating the infinite bus voltage with respect to the internal voltage. Okay therefore the total reactance which comes will be  $X_d'$  plus  $X_E$  where  $X_E$  is the reactance of the transmission line okay.

(Refer Slide Time: 11:14)

The complex power behind  $X_d'$  is given by

$$S' = P + jQ' = \tilde{E}' \tilde{I}_t^*$$

$$= \frac{E' E_B \sin \delta}{X_T} + j \frac{E' (E' - E_B \sin \delta)}{X_T} \quad (18.2)$$

Then the complex power behind  $X_d'$  is given by  $S'$ ,  $S'$  is equal to  $P$  plus  $j$  times  $Q'$  you can call it  $P'$ . Okay this is  $E'$  into  $I_t$  complex I am sorry  $I_t$  conjugate,  $I_t$  conjugate that is the complex power is  $P'$  plus  $j$  times  $Q'$  and this is obtained by multiplying this voltage  $E'$  by conjugate of  $I_t$ , okay when you make the simplifications.

We can write down the expression for air gap torque. Now we all know actually that in case we neglect losses right then the air gap torque is equal to the the power output impairing your system that when you consider the per unit system then the power output at the terminal of the machine is same as the air gap torque. Okay and this is our standard power angle characteristic, now here at this stage I would like to mention that in case instead of having a non-salient pole machine, if we have a salient pole machine right then the power angle characteristic will be different from what is given here, it will have a another term which is known as the reluctance torque. Okay and one can write down the expression for the power angle but this is the primary requirement to start with. The next step is you will linearize you linearize the expression for air gap torque around an operating point.

(Refer Slide Time: 12:04)

With armature resistance neglected, the air gap power ( $P_e$ ) is equal to the terminal power ( $P$ ). In per unit air gap torque is equal to the air-gap power.

$$T_e = P = \frac{E' E_B}{X_T} \sin \delta \quad (18.3)$$

(Refer Slide Time: 13:56)

Linearizing about an initial operating condition represented by  $\delta = \delta_0$ .

$$\Delta T_e = \frac{\partial T_e}{\partial \delta} \Delta \delta = \frac{E' E_B}{X_T} \cos \delta_0 (\Delta \delta) \quad (18.4)$$

Our initial operating condition is characterized by the angle delta equal to delta naught that when we are operating and transferring certain amount of power right the initial value of delta is delta equal to delta naught, okay. The linearized equation is written in the form delta  $T_e$  is equal to partial derivative of  $T$  with respect to delta into delta delta where this expression is very simple there is only a  $T_e$  is function of function of one variable only here. We are assuming this  $E$  prime and  $E_B$  constant, okay. The infinite bus voltage assumed to be constant the voltage behind transient reactance is assumed to be constant the total line reactance is constant and therefore the

torque is function of delta only one variable and therefore when you obtain the small change in the air gap torque  $\Delta T$  is equal to partial derivative of  $T$  divided delta into delta.

Therefore, here basically this partial derivative becomes derivative term itself right there is no other you can say parameter on which the  $T_e$  depends okay but in case actually these are also variables right then when I talk about this term it is the partial derivative with respect to delta not delta when you take other terms also then you have to write the partial derivative of this quantity with respect to not delta say when you take this partial derivatives there there so many variables will be there.

You have to keep on taking all the variables then you will have delta delta delta  $E$  prime delta  $E$  prime like this it is basically it is actually the Taylor series exponents time to expand the equation around the operating condition right. Now we come to the basic equations of motion, we have developed earlier the swing equation of the synchronous generator and the swing equation is a second order non-linear differential equation. This equation can be represented by two first order linear I am sorry 2 first order non linear differential equations it { it will continue to be non linear.

(Refer Slide Time: 16:43)

The equations of motion are

$$p\Delta\omega_r = \frac{1}{2H}(T_m - T_e - \underline{K_D}\Delta\omega_r) \quad (18.5)$$

$$p\delta = \omega_0 \Delta\omega_r \quad (18.6)$$

These two equations are written here as  $p \Delta\omega_r$  equal to  $\frac{1}{2H} T_m$  minus  $T_e$  minus  $K_D \Delta\omega_r$  and second equation is  $p \delta$  equal to  $\omega_0 \Delta\omega_r$ , where  $\Delta\omega_r$  is the deviation of the rotor speed with respect to synchronous speed right. The  $K_D$  is the damping torque coefficient to for the sake of completeness right, we include damping term also well earlier when we discussed actually the  $K_D$  was not explicitly included in the equation but the complete equation is in this form.

Now when the equation is written in this form the speed deviation  $\Delta\omega_r$  is expressed in per unit,  $\Delta\omega$  is expressed in per unit, the mechanical torque, electrical torque are also expressed in per unit. We know how to define the initial constant  $H$  the time in this equation is the time instead of putting in per unit we always prefer to express time in second is right and therefore, the second equation has  $p\Delta\omega$  equal to  $\omega_{naught}$  into  $\Delta\omega$ .

Now these are the 2 basic equations around which the we will be you can say developing the small signal model using these equations, small signal model and studying the basic concepts of small signal stability. Now you what we do is that this these two equations that is 18.5 and 18.6, we will linearize around the operating condition okay.

(Refer Slide Time: 19:39)

Linearizing Eq(18.5) and substituting the value of  $\Delta T_e$

$$p\Delta\omega_r = \frac{1}{2H} (\Delta T_m - \underline{K_s \Delta\delta} - \underline{K_D \Delta\omega_r}) \quad (18.7)$$

Now to linearize this around the operating condition one assumption here which we are making is that there is a mechanical power input remains constant that is  $T_m$  is constant right and  $T_m$  is equal to the initial power output that is  $T_{eo}$ . Okay and therefore when we talk about the small perturbations our equation will become  $p\Delta\omega_r$  equal to  $\frac{1}{2H} \Delta T_m$  minus  $K_s \Delta\delta$  minus  $K_D \Delta\omega_r$  this  $\Delta T_m$  is considered to be a change in mechanical torque.

Okay but generally this change is included in the model included in the model to obtain the dynamic performance by giving a small change in the mechanical torque right. Otherwise the mechanical torque remains constant this  $\Delta T$  term has been replaced by  $K_s \Delta\delta$  and this term  $K_s$  is synchronizing torque coefficient right and what will the unit of this coefficient unit per unit torque. Now in this equation actually be the  $\Delta\delta$  is expressed in radians electrical radians. Okay similarly, the unit for  $K_D$  the torque in per unit per, sir in previous

equation  $T \delta$  equals to  $\omega_r$  naught into  $\delta$   $\omega_r$ , so all this equation comes because  $T \delta$  equal to I think  $\omega_r$  naught plus  $\delta \omega_r$   $\delta r$ . Now if you see the basic equation it is like this,  $d\delta$  by  $dt$  is equals to  $\omega_r$  minus  $\omega_r$  naught that  $\omega_r$  naught is the synchronous speed okay. Now what we do here is that this difference we do not by in fact actually this speed actual speed is called  $\omega_r$  is the speed of the rotor. Okay this will do not this difference is noted by  $\delta \omega_r$ . Now what we do is that divide this by  $\omega_r$  naught, so that this quantity becomes in per unit and multiplied by  $\omega_r$  naught.

(Refer Slide Time: 21:34)

$$\begin{aligned}\frac{d\delta}{dt} &= \omega_r - \omega_0 \\ &= \frac{\Delta\omega_r}{\omega_0} \omega_0 \\ \frac{d\delta}{dt} &= \Delta\omega_r \omega_0 \\ \frac{2H}{\omega_0} \frac{d\omega_r}{dt} &= P_a\end{aligned}$$

So that I can represent  $d\delta$  by  $dt$  as  $\delta \omega_r$  into  $\omega_r$  naught while this  $\delta \omega_r$   $r$  is expressed in per unit. Okay while in this equation in this whole equation  $\delta$  is expressed in electrical radians because when you solve these problems, you have to be very clear about the units. Okay see originally when you see the our swing equation right, it is of the form  $d\omega_r$  divided  $dt$   $d\omega_r$  divided by  $dt$   $1$  upon  $2$ , I am sorry  $2H$  divided by  $s$   $2H$  divided by  $\omega_r$   $\omega_r$ , okay equal to accelerating power okay.

Now here when I express this  $\omega_r$  in per unit this is this is  $\omega_r$  naught not  $\omega_r$  this is  $\omega_r$  naught this is  $\omega_r$  right then this term is combined here. Okay so that I have this coefficient equal to  $2H$  only that is that is when you write the equation in this form,  $2H d\omega_r$  by  $dt$  equal to  $P_a$ . Okay here the this  $\omega_r$  is a per unit further  $\omega_r$  can be represented as  $\omega_r$  naught plus  $\delta \omega_r$  that the  $\omega_r$  naught is in this particular case when it is per unit  $\omega_r$  naught will become  $1$  that is you can put there is a  $1$  plus  $\delta \omega_r$  therefore, when you substitute this expression here I can write down the equation as  $2$  times  $H$   $d$  by  $dt$  of  $\delta \omega_r$  equal to  $P_a$ , is it okay that is that is since we know actually the derivative of this  $1$  is  $0$  therefore  $d$  by  $dt$  of  $\delta \omega_r$  is same as  $d\omega_r$  by  $dt$  and that is why when you look at the swing equation which we have written here.

(Refer Slide Time: 23:58)

$$2H \frac{d\omega_r}{dt} = P_a$$
$$\omega_r = \omega_0 + \Delta\omega_r$$
$$= 1 + \Delta\omega_r$$
$$2H \frac{d}{dt} \Delta\omega_r = P_a$$

Okay original swing equation this is not a linearized equation we can write down this delta omega r. Okay is it clear actually ah these 2 equations are very important actually because when you solve a given problem right the it is very important to understand that how the quantities are expressed what quantities are in per unit? what the unit of time? what is the unit of delta? what is the unit of speed deviation? all these terms are very important. Okay now when you look at this equation.

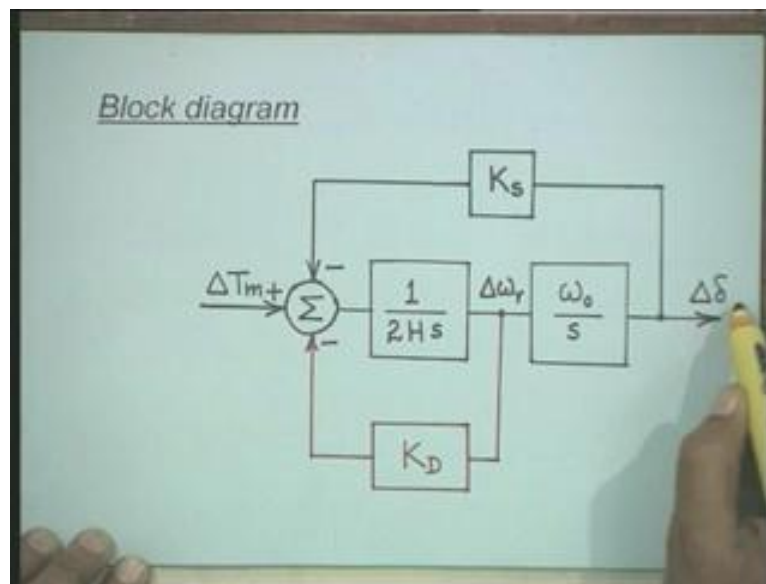

(Refer Slide Time: 26:07)

Linearizing Eq(18.5) and substituting the value of  $\Delta T_e$

$$P\Delta\omega_r = \frac{1}{2H} (\Delta T_m - \underline{K_s \Delta\delta} - \underline{K_D \Delta\omega_r}) \quad (18.7)$$
$$s \Delta\omega_r(s) = \frac{1}{2H} (\Delta T_m(s) - K_s \Delta\delta(s) - K_D \Delta\omega_r(s))$$
$$\Delta\omega_r(s) = \frac{1}{2H} ( \quad \quad \quad )$$

This is an equation in terms of small variations of speed angle and mechanical torque, okay and therefore we can take the Laplace transform of this equation right. When you take the Laplace transform it will become something like this  $s \Delta \omega_r$ ,  $s$  equal to  $1$  upon  $2H \Delta T_m(s)$ , okay minus  $K_s$  times  $\Delta \delta$  minus  $K_D$  times  $\Delta \omega_r$  that is in this equation all these variables are the Laplace transform. Okay and therefore now what we can do is that we can write down  $\Delta \omega_r$  as  $1$  upon  $2H$  times this whole expression okay.

(Refer Slide Time: 27:38)

Now this equation is represented in the block diagram form here at this **summing** at this summation point we have  $\Delta T_m$  minus  $K_s$  times  $\Delta \delta$  that is your  $\Delta T_e$  that is  $\Delta \delta$  is here  $\Delta T$  and  $K_D$  times  $\Delta \omega_r$ . Now when I represent this in the block diagram form all these variables are the Laplace transform but for the sake of convenience, we may not write  $\Delta \delta$  as  $\Delta \delta$  with  $s$ . Okay but we understand that in the block diagram or the transfer function model all the variables which we represent they are the Laplace transform of the original variables. Okay  $\Delta T_m$  also  $\Delta T_m(s)$  therefore this is the summation point where we derive a quantity which is given in this bracket  $\Delta T_m$  minus  $K_s \Delta \delta$  minus  $K_D \Delta \omega_r$ .

Now this quantity when it is multiplied, now here it is  $2$  times  $H_s$  when you multiply this by this block is  $1$  upon  $2$  times  $H_s$  right, we get  $\Delta \omega_r$  here okay. Now the next step here is to linearize the second equation. Our second equation was  $p \Delta \theta$  equal to  $\omega_o \Delta \delta$  but this  $\Delta \theta$  is our **our** actually the  $\Delta \theta$  can be written as  $\Delta \theta_o$  plus  $\Delta \theta$  and therefore  $p \Delta \theta$  is same as  $p \Delta \theta$  because  $\Delta \theta_o$  is constant that is if you take the derivative of this term that is  $d \Delta \theta$  by  $dt$  right then this comes out to be same as  $d \Delta \theta$  by  $dt$ .

(Refer Slide Time: 29:09)

$K_s$  is the synchronizing torque coefficient

$$K_s = \left( \frac{E' E_B}{X_T} \right) \cos \delta_0 \quad (18.8)$$

Linearizing the Eq(18.6) we get,

$$p \Delta \delta = \omega_0 \Delta \omega_r \quad (18.9)$$
$$\delta = \delta_0 + \Delta \delta$$

(Refer Slide Time: 29:53)

$K_s$  is the synchronizing torque coefficient

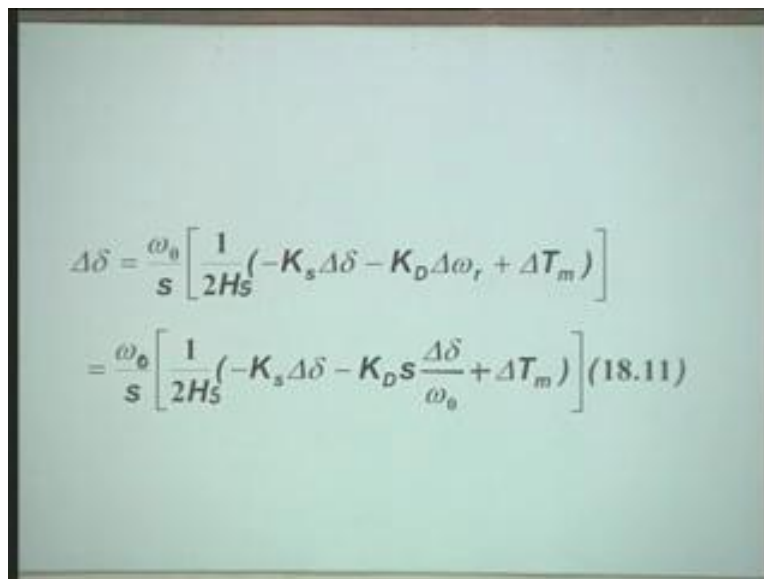

$$s \Delta \delta(s) = \Delta \omega_r(s) \omega_0$$
$$\Delta \delta(s) = \frac{\omega_0}{s} \cdot \Delta \omega_r(s)$$

Okay now if you take the Laplace transform of this equation then it will be  $s$  times,  $s$  times delta delta  $s$  equal to delta omega  $r$   $s$  into omega naught therefore, I can now write down delta delta  $s$  equal to omega naught by  $s$  into delta omega  $r$   $s$ . Okay therefore the the speed deviation right is related to the angle deviation by this transfer function omega naught by  $s$ . Okay and therefore in this block diagram the this transfer function omega naught by  $s$  relates the angle deviation that is delta delta to delta omega  $r$ . Okay and therefore this block diagram is extremely important to understand the small signal stability of a power system because we will be developing the

complete model including including additional blocks to this basic block diagram right. Now the next step to understand the whole thing is that we develop a characteristic equation characteristic equation of this system right.

Now to develop the characteristic equation, we can make use of this block diagram and relate this output delta delta this output delta delta is to be related to change in mechanical this is the input right therefore, if you look at this block diagram input is changed in mechanical torque output is delta delta therefore this is a single input, single output system. Okay they normally they call it SISO single input single output system and you can simplify this model and obtain a simple transfer function relating the delta delta to delta  $T_m$  that is first we write down what is delta delta as omega naught by s 1 upon 2 time Hs into this whole quantity which is delta  $T_m$  minus  $K_s$  delta delta minus  $K_D$  delta omega, okay.

(Refer Slide Time: 32:35)

$$\Delta\delta = \frac{\omega_0}{s} \left[ \frac{1}{2Hs} (-K_s\Delta\delta - K_D\Delta\omega_r + \Delta T_m) \right]$$

$$= \frac{\omega_0}{s} \left[ \frac{1}{2Hs} (-K_s\Delta\delta - K_Ds \frac{\Delta\delta}{\omega_0} + \Delta T_m) \right] \quad (18.11)$$

Now in this equation what we do is that we replace this delta omega r, delta omega r by delta delta upon omega naught into s right because this relationship is there in the block diagram. You can see this block diagram relationship delta delta is equal to omega naught by s into delta omega r right. So that when you look at this equation we have now delta  $T_m$  delta delta and other constant terms.

Okay and therefore when you rearrange the whole thing, you can write the equation in this form s square delta delta  $K_D$  by 2H s delta delta plus  $K_S$  by 2H omega naught delta delta equal to omega naught by 2H delta  $T_m$  right. Now when you equate this expression to 0, we get the characteristic equation for the system that this is this is the input input term right.

(Refer Slide Time: 33:41)

Rearranging, we get

$$s^2(\Delta\delta) + \frac{K_D}{2H}s(\Delta\delta) + \frac{K_S}{2H}\omega_0(\Delta\delta) = \frac{\omega_0}{2H}\Delta T_m \quad (18.12)$$

(Refer Slide Time: 34:24)

The characteristic equation is,

$$s^2 + \frac{K_D}{2H}s + \frac{K_S\omega_0}{2H} = 0 \quad (18.13)$$

Therefore to obtain the characteristic equation we can use this expression therefore the characteristic equation is in the form  $s^2$  plus  $K_D$  by  $2H$ s plus  $K_S$  omega naught by  $2H$  equal to 0. Since the system which we have considered is a second order system therefore characteristic equation is also a second order characteristic equation. Now you can see here the coefficients are depending upon the damping term  $K_D$  the system inertia constant  $H$  the synchronizing torque coefficient  $K_S$ . Now these are the system parameters further you can easily see that  $K_S$  depends upon the operating condition. Okay it also depends upon the line reactance

whether the expression for  $K_s$  is for this single machine infinite bus system the expression for synchronizing torque coefficient is  $E' \sin \delta_0$  divided by  $X_t$  into  $\cos \delta_0$  right and therefore we can easily see here actually that in this characteristic equation the coefficients are function of loading that is system operating condition and system parameters also the  $X_t$  depends upon the line reactance.

(Refer Slide Time: 36:01)

The characteristic equation is in general form of,

$$s^2 + \frac{K_D}{2H}s + \frac{K_S \omega_0}{2H} = 0 \quad (18.14)$$

Similarly, it depends upon direct axis transient reactance right, now when this equation is similar to our standard equation in this form  $s^2 + 2\zeta\omega_n s + \omega_n^2 = 0$  and you can identify identify that this coefficient  $2\zeta\omega_n$  is equal to  $K_D$  by  $2H$ . Similarly, this  $\omega_n^2$  term that is this term is equal to  $K_S \omega_0$  by  $2H$  while this  $\omega_n^2$  term is equal to  $K_S \omega_0$  divided by  $2H$ .

Okay now when you obtain the roots of this characteristic equation right the roots can be written as  $s_1, s_2$  the small  $s$   $s_2$  equal to  $-\zeta\omega_n \pm j\omega_n \sqrt{1 - \zeta^2}$  that is in this case the roots will depend upon whether they are complex conjugate or real on the value of  $\zeta$ , if  $\zeta$  is greater than 0 and less than 1 right. We will get these 2 roots as complex conjugate roots right.

Now a system whose  $\zeta$  is greater than 0 and less than equal to one right we say that the system is under damped. A system whose  $\zeta$  is equal to 1 is critically damped and a system whose  $\zeta$  is greater than 1 is over damped right and a system whose  $\zeta$  is less than 0 is unstable it is in negative damping system is unstable right in any system, we have to ensure that the damping is adequate.

(Refer Slide Time: 37:09)

$$s_{1,2} = -\zeta\omega_n \pm j\omega_n\sqrt{1-\zeta^2}$$

$0 \leq \zeta \leq 1$  underdamped  
 $\zeta = 1$  critically damped  
 $\zeta > 1$  overdamped

So that the oscillations which are generated are damped, whenever we design the controller for the system we have to achieve certain minimum damping for all the modes which are present in the system right. Now here we can also give some more interpretation to the damping term zeta that is if you plot these roots in the s plane then assuming that damping zeta is positive the roots will appear in the s plane because here we, so the real part we call it sigma.

(Refer Slide Time: 39:49)

We call this as omega and this axis and any any root is written as sigma plus minus j omega right. Now if the system is a stable system like having its complex conjugate or the roots lying in the left half of the s plane then this term that is this can be this can be is written equal to how much zeta omega n while this term will be equal to how much omega n square root of 1 minus zeta square what will be this quantity omega n therefore, this omega n is the distance of the root from the origin okay.

(Refer Slide Time: 42:15)

Now if you find out this if you look at this angle theta right then cosine theta is equal to zeta right therefore whenever we perform this Eigen value analysis of the system. We we can draw in the s plane a line which will represent certain value of zeta that is you can that is suppose this is your s plane right and if I say that this line represents zeta equal to say .1, this line will represent zeta equal to say something more than .1, .2 like this.

Now in case all the roots lie on this side of this line it means each mode or there is no mode whose damping is less than .2 right therefore whenever we design the control for this for improving the system stability particularly the AVR tuning or power system stabilizer tuning right, we perform the root locus analysis okay and vary the parameters like gain setting and see actually that you get the optimum performance but at the same time you ensure actually that no root is having its damping less than the desired value that therefore this this is a very important way to to ensure that we do not go to a stage where any of the roots is less than or any of the roots is having its damping less than desired value okay.

Now for this system which we are considering here the omega n is the natural frequency of oscillation it is given by this formula omega n is equal to square root of  $K_s \omega_n$  and damping ratio zeta is one upon 2 times  $K_D$  divided by square root of  $K_s \omega_n$ . Okay these 2o terms you can derive and see that you get the value of omega n and zeta

like this. Now the next point which we will study is, see this the two differential equations which we have derived the linearized differential equations one differential equation was written in this form, okay the.

(Refer Slide Time: 43:55)

The undamped natural frequency is

$$\omega_n = \sqrt{K_S \frac{\omega_0}{2H}} \text{ rad/s} \quad (18.15)$$

And the damping ratio is

$$\xi = \frac{1}{2} \frac{K_D}{\sqrt{K_S 2H \omega_0}} \quad (18.16)$$

(Refer Slide Time: 45:17)

Writing Eq(18.7) and Eq(18.9) in vector matrix form,

$$\frac{d}{dt} \begin{bmatrix} \Delta \omega_r \\ \Delta \delta \end{bmatrix} = \begin{bmatrix} -\frac{K_D}{2H} & -\frac{K_S}{2H} \\ \omega_0 & 0 \end{bmatrix} \begin{bmatrix} \Delta \omega_r \\ \Delta \delta \end{bmatrix} + \begin{bmatrix} \frac{1}{2H} \\ 0 \end{bmatrix} \Delta T_m \quad (18.10)$$

$$\dot{X} = AX + Bu$$

Similarly, we are written data written the second differential equation in the linearized form, okay. Now you can arrange these two differential equations right and write the model in the vector matrix form that is finalizing the stability of the system right the most convenient form of

representing the model is vector matrix form that is we write the model in the form of  $\dot{X} = A_x X + B_u u$  right.

Now these two equations which we have derived can be arranged in this form that is  $\frac{d}{dt} \omega_r = -\frac{K_D}{2H} \omega_r - \frac{K_s}{2H} \delta + \frac{1}{2H} T_m$  second equation is  $\frac{d}{dt} \delta = \omega_r$  that is all. Okay therefore, these two equations which we have derived can be written in the vector matrix form and when we make use of the the say mat lab for analyzing the system performance right then we can find out the Eigen value of the system matrix  $A$  right for studying the stability characteristic of the system right.

Now you have to understand very clearly here that this matrix  $A$  is function of function of operating condition and system parameters this I will be you know emphasizing again and again here that whenever you write down the model in the form  $\dot{X} = A_x X + B_u u$  right then the basic stability characteristics are determined from the system  $A$  matrix. Okay therefore live let me summarize here that what we have done till now is we have developed the small signal model for the machine infinite bus system and we have represented this model in the form that is vector matrix form  $\dot{X} = A_x X + B_u u$ .

We can write down the  $A$  matrix we can write down the  $B$  matrix and the state variables in this model are  $\omega_r$  and  $\delta$ , these are the state variables while  $\delta$  and  $T_m$  in this case is a input, okay. Now I will just give one more important information that the importance of this term  $2H$  okay, now to understand this importance of this term  $2H$ , let us look at our swing equation again.

(Refer Slide Time: 48:12)

Mechanical starting time

$$\frac{d \omega_r}{dt} = \frac{1}{2H} T_a$$

Where  $\omega_r$  and  $T_a$  are in per units

Our swing equation is  $d\omega_r/dt = 1/2H T_a$  okay, where  $\omega_r$  is expressed in per unit, okay. Now now suppose you have a synchronous generator and which is at stand state 0 speed okay and if you apply the rated torque then in how much time the synchronous generator will attain its the rated speed right. Now to obtain the time in which this synchronous generator will attain its rated speed can be obtained by integrating this equation that is you integrate this equation assume  $T_a$  equal to 1 per unit okay,  $T_a$  equal to 1 per unit and just tell me in uh quickly in how much time the synchronous generator will attain its rated speed.

Okay the synchronous generator will attain its rated speed starting from 0 towards rated value when it is applied with a rated accelerating torque that is  $T_a$  is equal to 1 per unit and therefore this time  $2H$  is also denoted as the mechanical starting time of the synchronous generator that is  $T_M$  is equal to  $2H$  therefore, if you see in the model we have a term  $1/2H$  therefore this  $2H$  is similar to a time constant and is the mechanical starting time of the synchronous generator in literature you will find actually that many times we represent this term this  $T_M$  by a symbol capital  $M$  that is you will find actually when you read the literature that this block  $1/2H$  is also represented as  $1/M_s$ .

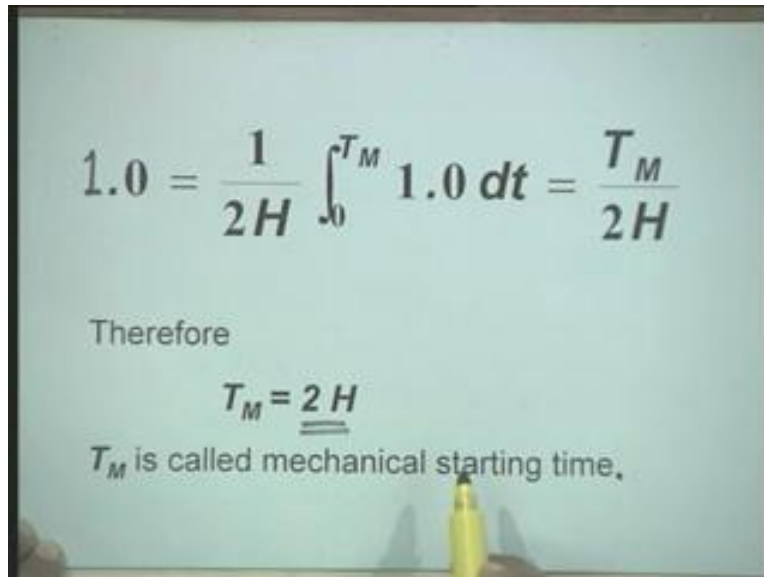

(Refer Slide Time: 49:42)

Integrating with respect to time we get

$$\omega_r = \int_0^t T_a dt$$

Let  $T_M$  be the time required for the rated torque to accelerate from stand still to rated speed.

(Refer Slide Time: 49:57)

$$1.0 = \frac{1}{2H} \int_0^{T_M} 1.0 dt = \frac{T_M}{2H}$$

Therefore

$$T_M = \underline{2H}$$

$T_M$  is called mechanical starting time,

Now here you should not get confused with the term M, the angular momentum of the rotor right the M here is actually the in the small del will be equal to 2H and which is the mechanical starting time of the synchronous generator rotor when it is subjected to a rated torque. Similarly, if the machine is running at constant speed a rated speed and if you apply a retarding torque equal to the rated torque then its speed will come down to 0 in a time equal to 2H right.

Therefore, that also gives the information that how much time the machine will take to retard from its lateral speed to 0 speed therefore with this today I will conclude my presentation by saying that we have developed a linear model of machine infinite bus system considering constant field flux linkages. Okay we have also studied the ah the the the importance of damping ratio zeta right and whenever we design the system right the zeta is going to be one of our design parameters, okay. Thank you!
