Limitations of PID Controller

Welcome to the lecture on Limitations of PID controllers. PID controller is found to be work house in process industries. Is there any limitation associated with a PID controller? That we shall see in this lecture.

(Refer Slide Time: 00:42)

PID controller can be given in various forms, in series, in parallel form. When it is expressed in series form or in parallel form, it might be subjected to structural limitation.

(Refer Slide Time: 01:04)

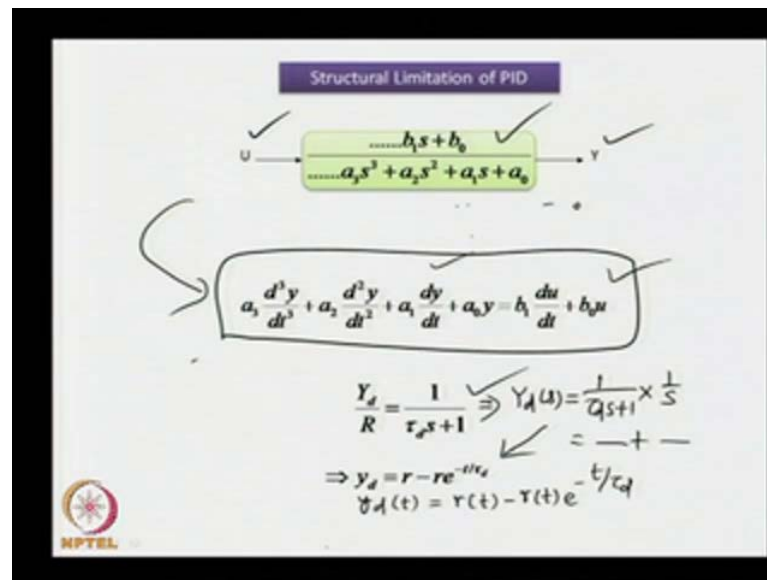

Let us consider, first a plant dynamics given in the form of $G(s)$ equal to $b_m s^m + b_{m-1} s^{m-1} + \dots + b_1 s + b_0$ upon $a_n s^n + a_{n-1} s^{n-1} + \dots + a_1 s + a_0$. So, we have described the dynamics of a process in this polynomial form, in this transfer function form.

When the dynamics is expressed in this form, since the input to the process is U and the output from the process is Y , the dynamics of the **process** same process can be also expressed in differential equation form. As an equation giving us $a_n \frac{d^n y}{dt^n} + \dots + a_1 \frac{dy}{dt} + a_0 y = b_m \frac{d^m u}{dt^m} + \dots + b_1 \frac{du}{dt} + b_0 u$. Why we are trying to get the dynamics expressed in the differential equation form? That helps us in analyzing the dynamics of a process and the limitations of a controller employed for controlling the process.

Let us first assume that, we have got a third-order process which dynamics is given by a numerator as $b_1 s + b_0$ upon a denominator as $a_3 s^3 + a_2 s^2 + a_1 s + a_0$. Cross multiplying and taking the inverse Laplace transform gives us the differential equation of the third-order system as $a_3 \frac{d^3 y}{dt^3} + a_2 \frac{d^2 y}{dt^2} + a_1 \frac{dy}{dt} + a_0 y = b_1 \frac{du}{dt} + b_0 u$. So, this differential equation gives us the dynamics of a third-order system in time domain.

(Refer Slide Time: 04:22)

Next, let us make some assumption. Let us assume that, we wish to have a desired performance from the system, a first-order performance from the system. What is a first-order performance? Suppose, the reference input is like this and the desired output has to be of this form, a first-order response form, as so as possible with high rise time, less settling time and to know **our (())**. So, this set of response often can be represented by a first-order filter given as 1 upon $\tau_d s + 1$. This is the time constant one can find from here, when you have got 0.63 percent of the reference value. So, that gives us the time constant τ_d over here.

So, assuming that, the closed loop system has to have a suitable response of this form, Y_d upon R equal to 1 upon $\tau_d s + 1$, we get the expression $Y_d s$ equal to 1 upon $\tau_d s + 1$ times $R s$. So, when we employ you need set point inputs to the system or you need step reference inputs to the system, at that time $R s$ becomes 1 upon s . Thus, we get $Y_d s$ is equal to 1 upon $\tau_d s + 1$ times 1 upon s , which again using the partial fraction expansion and inverse Laplace transform gives us an expression in the time domain as $Y_d t$, the desired response in time domain $Y_d t$ equal to $r t$ minus $r t e^{-t/\tau_d}$ to the power minus t upon τ_d .

Now, with small τ_d , what we will get? We will get high rise time for the system; with large τ_d , we will get large rise time. So, often it is desirable to have small τ_d time constant for the closed loop system. Thus, we have got the desired response for a closed

loop system with the process dynamics given as this one as y_d is equal to r minus r_e to the power minus t upon τ_d .

(Refer Slide Time: 07:35)

Now, and we have got the closed loop control system shown in this fashion. So, we have a process $G(s)$ and the controller $G_c(s)$ a PID controller; let the PID controller be a parallel, PID controller this giving us its dynamics in the form of $G_c(s)$ is equal to $K_p \left(1 + \frac{1}{T_i s} + T_d s \right)$ plus one upon $T_i s$ plus $T_d s$.

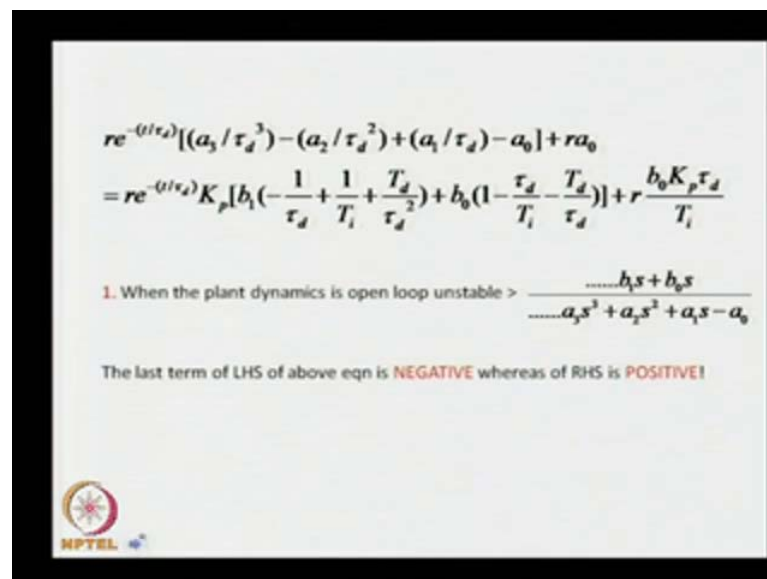

(Refer Slide Time: 08:00)

Then, since the PID controller has got inputs $e(t)$ and output $u(t)$ and here we have got the PID dynamics, therefore, expression for the PID controller output $u(t)$ in time domain can be obtained as $K_p e(t) + K_p \text{ upon } T_i \int_0^\infty e(t) dt + K_p T_d \frac{de(t)}{dt}$. What is $e(t)$? It is nothing but, the signal we get from the difference of the desired output and the actual output, desired output and the actual output. So, substituting $e(t)$ over there, we get the expression for $u(t)$ as $k_p r(t) - y(t) + k_p \text{ upon } T_i \int_0^\infty r(t) - y(t) dt + K_p T_d \frac{dr(t) - dy(t)}{dt}$, that has been shown over here (Refer Slide Time: 09:57).

So, the conventional PID controller, the parallel PID controller output can be expressed in this form, but we wish to have some desired output from the closed loop system, which is nothing but, y equal to $y_d(t)$ $y(t) = y_d(t)$ $y_d(t) = r(t) - r(t)$, $e(t)$ to the power minus t upon τ_d .

(Refer Slide Time: 11:10)

$$re^{-t/\tau_d} [(a_3/\tau_d^3) - (a_2/\tau_d^2) + (a_1/\tau_d) - a_0] + ra_0$$

$$= re^{-t/\tau_d} K_p [b_1(-\frac{1}{\tau_d} + \frac{1}{T_i} + \frac{T_d}{\tau_d^2}) + b_0(1 - \frac{\tau_d}{T_i} - \frac{T_d}{\tau_d})] + r \frac{b_0 K_p \tau_d}{T_i}$$

1. When the plant dynamics is open loop unstable > $\frac{b_1 s + b_0}{a_3 s^3 + a_2 s^2 + a_1 s - a_0}$

The last term of LHS of above eqn is **NEGATIVE** whereas of RHS is **POSITIVE**!

So, substituting y equal to y_d $y_d(t) = r(t) - r(t)$ $e(t)$ to the power minus t upon τ_d and the above u in the differential equation dynamics for the process, we obtain a 3 d 3 y upon $d t^3$ plus $a_2 d^2 y$ upon $d t^2$ plus $a_1 d y$ upon $d t$ plus $a_0 y$ is equal to $b_1 d u$ upon $d t$ plus $b_0 u$ expressed in the form of r e to the power minus t upon τ_d times a_3 upon τ_d^3 minus a_2 upon τ_d^2 plus a_1 upon τ_d minus a_0 plus $r a_0$; which is equal to r e to the power minus T upon τ_d k_p times b_1 minus 1

upon τ_d plus 1 upon τ_d times T_i plus T_d upon τ_d square plus b_0 times 1 minus τ_d upon T_i minus τ_d upon t times τ_d upon t plus r times b_0 k_p τ_d upon T_i .

How do we obtain this expression? It is very important to get this expression, expressed in correct form because, the structural limitation of a PID controller can be evaluated properly provided this expression has been obtained accurately. So, substitution of Y_d and u over here will definitely the equation (Refer Slide Time: 12:30).

(Refer Slide Time: 12:39)

$$a_3 \frac{d^3 y}{dt^3} + a_2 \frac{d^2 y}{dt^2} + a_1 \frac{dy}{dt} + a_0 y = b_1 \frac{du}{dt} + b_0 u$$

$$y = y_d = r - r e^{-t/\tau_d}$$

$$u = k_p(r-y) + \frac{k_i}{T_i} \int_0^t (r-y) dt + k_p T_d \frac{d(r-y)}{dt}$$

$$\frac{du}{dt} = -k_p y + \frac{k_i}{T_i} (r-y) + k_p T_d \frac{d^2(r-y)}{dt^2}$$

$$= -k_p(r - r e^{-t/\tau_d}) + \frac{k_i}{T_i} r e^{-t/\tau_d} + k_p T_d \frac{d^2(r - r e^{-t/\tau_d})}{dt^2}$$

$$\frac{dy}{dt} = \frac{r}{\tau_d} e^{-t/\tau_d}; \quad \frac{d^2 y}{dt^2} = -\frac{r}{\tau_d^2} e^{-t/\tau_d}$$

$$\frac{du}{dt} = \frac{r}{\tau_d} e^{-t/\tau_d} - \frac{r}{T_i} e^{-t/\tau_d} + \frac{k_p T_d}{\tau_d^2} e^{-t/\tau_d}$$

So, let us write down, how we obtain that one $a_3 \frac{d^3 y}{dt^3} + a_2 \frac{d^2 y}{dt^2} + a_1 \frac{dy}{dt} + a_0 y$ is equal to $b_1 \frac{du}{dt} + b_0 u$. Now, y will be equal to y_d , which is equal to r minus r e to the power of minus t upon τ_d and u is equal to $k_p r$ minus y plus k_p upon T_i integration of 0 to t , r minus y dt plus $k_p T_d \frac{d}{dt} r$ minus y upon dt . Then, $\frac{du}{dt}$ will give us minus $k_p y$ plus k_i upon T_i r minus y plus $k_p T_d$ times $\frac{d^2}{dt^2} r$ minus y upon dt^2 , substitute y equal to y_d that gives us minus $k_p r$ minus r e to the power minus t upon τ_d plus k_i by T_i r minus y .

So, r minus y will give you r e to the power minus t upon τ_d plus $k_p T_d$ double differentiation of r minus y will give us $\frac{d^2}{dt^2} r$ e to the power of minus t upon τ_d upon dt^2 , which can further be simplified and put in the right half. Similarly, we have got $\frac{dy}{dt}$ as $\frac{r}{\tau_d} e$ to the power minus t upon τ_d then, $\frac{d^2 y}{dt^2}$ will give us minus r τ_d square e to the power minus t upon τ_d and

third derivative of y will give us r upon tau d cube e to the power minus t upon tau d. So, substituting all these expressions in the left and right half of the dynamic equation, enables us finally to get this expression.

(Refer Slide time: 16:08)

$$re^{-(t/\tau_d)}[(a_3/\tau_d^3) - (a_2/\tau_d^2) + (a_1/\tau_d) - a_0] + ra_0 = re^{-(t/\tau_d)}K_p[b_1(-\frac{1}{\tau_d} + \frac{1}{T_i} + \frac{T_d}{\tau_d^2}) + b_0(1 - \frac{\tau_d}{T_i} - \frac{T_d}{\tau_d})] + r \frac{b_0 K_p \tau_d}{T_i}$$

1. When the plant dynamics is open loop unstable > $\frac{b_1 s + b_0}{a_3 s^3 + a_2 s^2 + a_1 s - a_0}$

The last term of LHS of above eqn is **NEGATIVE** whereas of RHS is **POSITIVE**!

$$G(s) = \frac{b_1 s + b_0}{a_3 s^3 + a_2 s^2 + a_1 s - a_0}$$

$$a_0 = \frac{b_0 K_p \tau_d}{T_i}$$

So, collecting the term enables us to get the final expression, expressed in the form of r e to the power minus t upon tau d time, a 3 upon tau d cubed minus a 2 upon tau d square plus a 1 upon tau d minus a 0 with the delay term like this plus a constant value plus r a, 0 a positive value keep in mind. And in the right half we get, r e to the power minus t upon tau d K p times b 1 times minus 1 upon tau d plus 1 upon T i plus t d upon tau d square plus b 0 1 minus tau d upon T i minus t d upon tau d plus r times b 0 k p tau d upon T i.

So, carefully look at the last two terms, why we concentrate on the last two terms? If you look at the expressions or the terms even in the left hand and right hand side of the equation, the term associated with the exponential term we will die down with time after sometime as time elapses, that will die down and finally, what will remain in steady state? We will get an expression of the form r a 0 is equal r b 0 K p tau d upon T i, which is again a 0 is equal to b 0 K p tau d upon T i.

This is very important (Refer Slide Time: 18:16); this expression carries much meaning as far as analysis of a closed loop control system is concerned. Let us consider few cases, when the plant is open loop unstable, when the plant is open loop unstable, how do we

get the dynamics of the plant expressed in the transfer function from? As far as the third-order dynamics is concerned, $G(s)$ will be given as $b_1 s$ plus b_0 upon $a_3 s^3$ plus $a_2 s^2$ plus $a_1 s$ minus a_0 . Earlier, we have seen this was plus a_0 and with plus a_0 , we have obtained the expression given as this (Refer Slide Time: 19:10).

Now, when the plant dynamics possesses instability or plant dynamics is open loop unstable, at that time we have got minus a_0 or anyone of the coefficient go negative. For simplicity let us assume that, a_0 is assuming a negative value, in that case what happens? When a_0 is assuming a negative value, is it possible to provide similar value in the right half of the equation with the help of control parameters? No, you see b_0 is positive as I assumed; now, what are the other parameters we have? τ_d cannot be negative; otherwise, the closed loop response will be unstable.

Now, we have freedom to choose K_p and T_i which are nothing but, the controller parameters. We have freedom to set any values for the controllers, not the other parameter. So, that way can we make K_p or T_i or both negative? No, we cannot make, if K_p is met negative, then we have got unstable controller; if T_i is met negative, again we have got an unstable controller. So, when the process is unstable and the controller become unstable, then **it will** the output will explode simply.

It will be very difficult to get any set of desire output from that control system. That is why when the plant dynamics is open loop unstable irrespective of any setting of the controller parameters. It is not possible to get a a_0 negative a minus a_0 value with the settings of controller parameters and therefore, the PID controller cannot successfully control unstable processes, that is the logical we can put forward. Simply the logical is that, when the process is unstable, **this right half this term**, the term of the right half cannot be make negative with the help of the controller parameters. Therefore, the PID controller has got limitation in controlling unstable processes.

(Refer Slide Time: 22:04)

$$re^{-t/\tau_d}[(a_3/\tau_d^3) - (a_2/\tau_d^2) + (a_1/\tau_d) - a_0] + ra_0$$

$$= re^{-t/\tau_d} K_p [b_1(-\frac{1}{\tau_d} + \frac{1}{T_i} + \frac{T_d}{\tau_d^2}) + b_0(1 - \frac{\tau_d}{T_i} - \frac{T_d}{\tau_d})] + r \frac{b_0 K_p \tau_d}{T_i}$$

2. When the plant dynamics is integrating > $\frac{b_1 s + b_0}{a_3 s^3 + a_2 s^2 + a_1 s}$

The last term of LHS of above eqn is ZERO whereas of RHS is POSITIVE!

$$G(s) = \frac{b_1 s + b_0}{a_3 s^3 + a_2 s^2 + a_1 s} = \frac{b_1 s + b_0}{s(a_3 s^2 + a_2 s + a_1)}$$

$a_0 = 0$

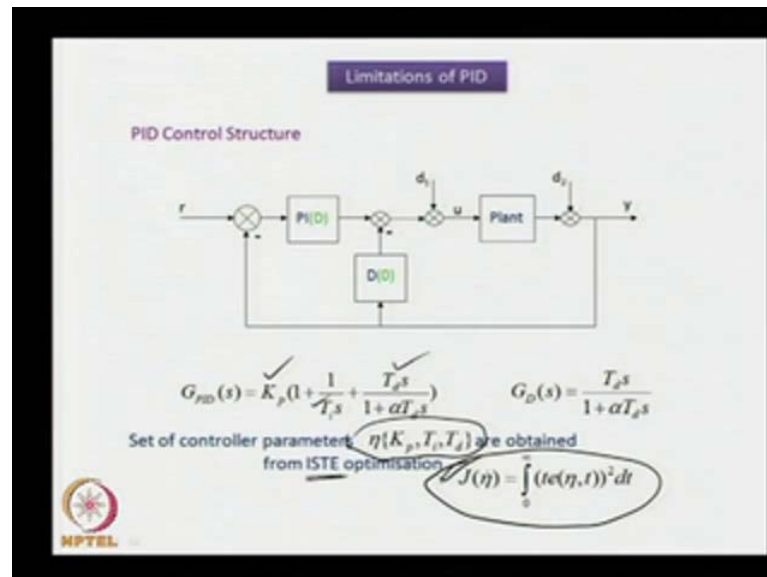

Let us see another case, when the plant dynamics is integrating. What do you mean by integrating? When the plant dynamics or the plant transfer function has got a pole located at the origin, then in that case, we tell that the process is integrating. For the integrating process, the dynamics in transfer function form can be given as $b_1 s$ plus b_0 upon $a_3 s^3$ plus $a_2 s^2$ plus $a_1 s$, which can further be written in the form of $b_1 s$ plus b_0 , upon s times $a_3 s^2$ plus $a_2 s$ plus a_1 .

So, we see that there is a pole located at the origin of the s plane. Thus giving us the process as an integrating process; in this case, what happens? a_0 becomes 0 **a 0 has become 0** is it possible to get the last term of the right half as 0 with the setting of the controller parameters? No, unless K_p is 0 or T_i is infinity we cannot make this last term to be 0 when a_0 equal to 0. That means, when the process is integrating in nature at that time, one needs to set P_p to 0 or T_i to infinity to get effective control of the closed loop system.

When K_p is set to 0, what will happen? We will get no controller in the loop, when T_i is set to 0, we have got no integral control in the system, when there is no integral control in the system, no integral control action in the system as expected, although we may get satisfactory set point response disturbance rejection cannot happen. So, for that case to have overall satisfactory closed loop performance of a system T_i or integral action cannot be neglected.

So, this is how the PID controller had got limitations; the controller parameters in spite setting of any values of controller parameter, we are not able to get the last term as 0. Thus the PID controller is found to have limitations in controlling unstable or integrating processes. Let us see through simulation results, whether that is really happening or not.

(Refer Slide Time: 25:12)

We shall consider a PID of this form (Refer Slide Time: 25:20), the PID controller may be PI and PID and its variant like PI in the feed forward path, with D in the feedback path, thus giving us also a PID controller or the PID in the feed forward path, with no inner feedback control or no feedback control at that time. So, we will consider different types of PID controller or PID and its variants in the simulation study.

So, let us assume that the form of the PID controller in the feed forward path be of this parallel PID controller form. And the derivative control in the feedback path is given by $G_d s$ equal to $T_d s$ upon one plus alpha $T_d s$, where again alpha is nothing but, the derivative filter constant. As far as this simulation study is concerned, to study the limitation of a PID controller, what we have done? We have tried to find optimum values for the PID gains, the K_p , T_i and T_d are estimated by minimization of the performance index known as is T e performance index. A set of parameters controller parameters can be employed and using the lustrum refer ship algorithm, that is not difficult to minimize the ISTE performance index and to obtain optimum controller parameters for PID control structure.

(Refer Slide Time: 27:19)

In the first simulation study, let us consider an integrating first-order plus time delay plant, given as $G(s)$ is equal to $0.0506 e^{-6s} / s$. So, this gives us the process dynamics of an integrating first-order plus dead time plant. This e^{-6s} gives us the time delay and we have got a very small gain, static gain for the system, in this case the gain is given as K equal to 0.0506, why this is first-order? It is because the denominator polynomial is of first-order.

For this process, using minimization of the performance index ISTE performance index, controllers have been obtained by various methods. Those controllers are given over here, a PID controller is designed where the proportional gain is 4.07 and the integral time constant is given as 27 seconds and the derivative time constant is given as 2.7 seconds. Using another technique, PID controller has been designed and in which case, the proportional gain is found to be 4.5, the integral time constant is found to be 8.94 seconds and the derivative time constant is of 3.54 seconds.

Another method, control design method has yielded a PID controller, with the proportional gain as 2 integral time constant as 31.1 seconds and derivative time constant as 1.57 seconds. Now, simulation results for the three situations, for the 3 PID controllers are shown over here (Refer Slide Time: 30:00). For the first PID controller, we obtain a response like this, which shows not only over shoot of more than 50 percent, but also a

high settling time, although the rise time is satisfactory, a high settling time and the disturbance rejection is also not smooth.

So, we do not get smooth step input responses, **why** that is not the case, why we are not getting smooth responses because the PID controller has got limitation in controlling integrating processes. Now, if I look at the performance given by the second controller, it is further inferior and the over shoot is more than 100 percent with very high settling time and oscillatory response.

Similarly, the third controller is giving little bit of satisfactory performance no doubt but, it is also having over shoot and under shoot of about 50 percent. Now, not only the time responses are quite unsatisfactory because, the responses are having multiple cycles and bonds, we do not get good settling time as well, which is one of the most desired things in closed loop control system.

The disturbances are rejected no doubts, static load disturbances had been rejected successfully, but the responses are not smooth. So, one can conclude from this plot that, the PID controllers have got limitations in controlling integrating processes. In spite of employing controller designed by various techniques, it has been found that, the time responses are quite oscillatory with very high over shoot and settling time.

Let us go to another example, in this example we consider a resonating second-order plus dead time plant (Refer Slide Time: 32:54). The plant dynamics or the process dynamics is given by a transfer function, which has got a time delay term $e^{-0.1s}$ in the numerator and $s^2 + 0.02s + 1$ in the denominator.

Why this process dynamics is known as a resonating second-order plus dead time dynamics? If I calculate the damping ratio, damping ratio can be calculated from this term, which gives us 0.02 upon 2 times root of 1, this is our ω_n square and this is given by $2\zeta\omega_n$. Therefore, ζ can be obtained as 0.002 upon 2 into root of 1 which gives us equal to 0.01.

So, we have got a very small damping in the system almost 0, therefore the system is oscillatory in nature. So, the system itself is oscillatory in nature. So, obviously, one needs to design carefully a controller for the resonating second-order plus dead time dynamic. So, let us consider one more example, where we have got a resonating second-

order plus dead time plant, with the transfer function given as $G(s) = \frac{e^{-0.1s}}{s^2 + 0.02s + 1}$.

Why this process is known as a resonating process? A process having resonance characteristics, if one look at carefully the denominator term, when it is compared with the standard denominator of a second-order transfer function form, $s^2 + 2\zeta\omega_n s + \omega_n^2$, we obtain the damping ratio to be of the value 0.02 divided by 2 times root of 1 which gives us 0.1, so 0.01. So, the damping ratio is found to be of value 0.01, which is almost negligible; as if the system has got no damping therefore, the dynamics of the system will be resonating or oscillating.

So, we have got an oscillatory system dynamics for which, one need to design carefully, proper PID controller for satisfactory closed loop performances. Various methods have been employed to design PID controller for this process dynamics, one such PID controller, where derivative control inner feedback controller is there, feedback derivative controller is there, is designed as PI controller in the feed forward path way 0.144 gain and 0.595 seconds time constant and the derivative field controller has got the parameters T_d equal to 0.61 second.

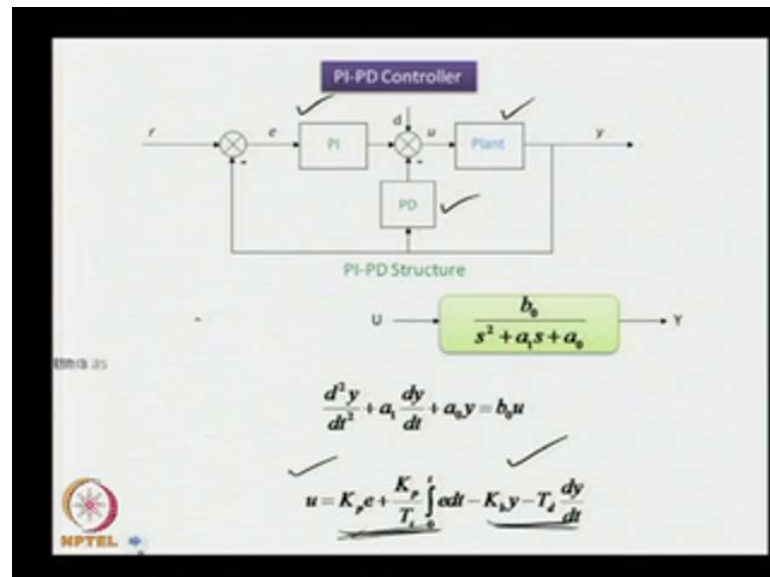

Thus, we have got a PID controller for the resonating process, employing another technique; a series PID controller has been designed, where the proportional gain is of same value 0.144 with integral time constant of 0.372 seconds and derivative filter time constant, derivative time constant of magnitude 5.613 seconds. A third PID controller designed has got the proportional gain as 0.144 integral, time constant of 4.4 seconds and derivative time constant of 1.1 seconds. Thus, we have got 3 different types of PID controllers designed by various techniques available in the literature.

Let us see the responses given by all those PID controllers. The PI with D feedback controller is given as this one, gives us a response shown by the solid line (Refer Slide Time: 38:28). So, this is the one we have got with the PI D controller. Let us analyze the time response of the controller, although it has got no over shoot, the response is sluggish and the settling time is very high. There are under shoots associated with the response and the response is not smooth.

Similarly, the PID controller given by b is giving us an oscillatory response and the third PID controller is giving us very poor time response, even the settling time is almost

infinite in this case. Thus we see that, the PID controller has got limitation in controlling certain type of processes, if the process is unstable, if the process is integrating, if the process is resonating, in those cases the PID controller fails, because it has got structural limitations in controlling unstable, integrating or resonating processes.

(Refer Slide Time: 40:05)

Let us consider a PI PD controller to alleviate the problems associated with a PID controller. One can employ a PI PD controller, in which case a PI controller is there in the feed forward path and a PD controller in the feedback path. Let us assume the process dynamics to have the transfer function expressed as b_0 upon s square plus $a_1 s$ plus a_0 . We are assuming a simple transfer function for the plant, for each in analysis although one is not **((divide))** to take any form of process dynamics in the analysis.

That will give us the dynamics of the process expressed in time domain as d^2y upon dt^2 plus $a_1 dy$ upon dt plus $a_0 y$ equal to $b_0 u$. Now, the PI PD controller dynamics will give us the control signal expressed in the form of u equal to $K_p e$ plus K_p upon T_i integration from 0 to t of e minus $K_b y$ minus $T_d dY$ upon dt . We have got a feed forward PI action and feedback, PD action given by the control signal.

(Refer Slide Time: 41:48)

$$u = K_p(r - y) + \frac{K_p}{T_i} \int_0^t (r - y) dt - K_b y - T_d \frac{dy}{dt}$$

Assuming, the desired closed loop response to be

$$\frac{Y_d}{R} = \frac{1}{\tau_d s + 1} \Rightarrow y_d = r - r e^{-t/\tau_d}$$

If perfect tracking is used, it is easy to write the plant dynamics as

$$r e^{-t/\tau_d} [-(1/\tau_d^2) + (a_1/\tau_d) - a_0] + r a_0$$

$$= r e^{-t/\tau_d} b_0 [K_p - \frac{K_p \tau_d}{T_i} + K_b - \frac{T_d}{\tau_d}] + r b_0 (\frac{K_p \tau_d}{T_i} - K_b)$$

Handwritten note: $a_0 = b_0 (\frac{K_p \tau_d}{T_i} - K_b)$

NPTEL logo

So, the control signal is made up of two components. With this control signal, we can find the expressions we have obtained earlier for the case of a PID controller, a series PID controller. A similar expression can be obtained with the exception that, the last term in the left half side of the equation is $r a_0$, we had got the same expression in earlier case also. Let me show we have got $r a_0$, whereas the right half had the last term expressed as $r b_0 K_p \tau_d / T_i$ but, when a PD control is employed, the last term becomes $r b_0$ times $K_p \tau_d / T_i$ minus K_b . This minus K_b is given by the PD controller; we assume the same desired response for the closed loop system as we had for the earlier case. This last term will enable us to compare with the left hand sides and get an expression of the form a_0 equal to $b_0 K_p \tau_d / T_i$ minus K_b .

(Refer Slide Time: 43:28)

$$re^{-(t/\tau_d)}[-(1/\tau_d^2) + (a_1/\tau_d) - a_0] + ra_0 \quad a_0 < 0$$

$$= re^{-(t/\tau_d)} b_0 [K_p - \frac{K_p \tau_d}{T_i} + K_b - \frac{T_d}{\tau_d}] + rb_0 (\frac{K_p \tau_d}{T_i} - K_b)$$

1. When the plant dynamics is open loop unstable $\Rightarrow \frac{b_0}{s^2 + a_1 s - a_0}$

$a_0 < 0 \rightarrow \frac{K_p \tau_d}{T_i} < K_b$

2. When the plant dynamics is open loop integrating $\Rightarrow \frac{b_0}{s(s + a_1)}$

$a_0 = 0 \rightarrow \frac{K_p \tau_d}{T_i} = K_b$

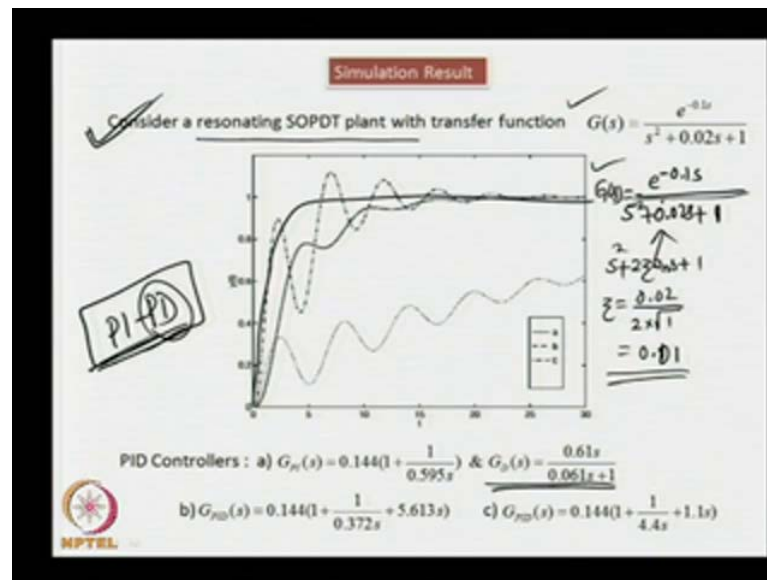

Let us see what we get from these last terms, when the plant dynamics is open loop stable, then a_0 becomes minus a_0 . For open loop unstable processes, its transfer function in simple form can be given as b_0 upon s^2 plus $a_1 s$ minus a_0 . Then a_0 is... then is it possible to get a negative value for this term when a_0 is negative. So, when a_0 is less than 0, what happens? Can we set this to less than 0? Yes, one can set with the help of the requirement that $K_p \tau_d$ upon T_i has to be less than K_b .

So, when $K_p \tau_d$ upon T_i is less than K_b , this term becomes negative and how we have got a_0 as negative? Equating the two, one can get the design parameters as well. So, the limitations with PID controller can be overcome in this fashion, if one uses a PI PD controller, then it is possible to get the last term as negative. Similarly, when the plant dynamics or the process is open loop integrating, in which case a_0 becomes 0 when $K_p \tau_d$ upon T_i becomes K_b , then we get this term to be 0 and since a_0 is 0 this two can be compared.

When a_0 is when a_0 is less than 0, then this first part has to be less than K_b , $K_p \tau_d$ upon T_i has to be less than K_b . So, what we have seen from this analysis that, employing a PI PD controller, it is possible to design controller parameters in such a way that, the closed loop performances can be obtained as per our wish, the closed loop performances can be satisfactory.

(Refer Slide Time: 46:20)

Let us see some example studies, simulation studies. If we look at, although we have got let us go back to the example, we had already consider during our analysis, we have got a D controller, although we do not have PI PD controller, we have got D controller in the feedback path, that is why we are getting a quite satisfactory; although it may not be so satisfactory, a quite satisfactory performance compared to the other two performance given by the PID controller.

A PID controller is giving us inferior responses, but a PID with D controller in the feedback is giving a little superior performance compared to the other two, had they been a PI PD controller, this response can further be improved and obtained in some convenient form. This response would become like this, what we wish to have from the closed loop system (Refer Slide Time: 47:24).

So, if one employs a PI PD controller then definitely, it is possible to obtain a response of this form from the closed loop control systems. Let us summarize what we have learned from this lesson, PID controller have got limitations in controlling certain processes like unstable process, integrating process and resonating process. PI PD controllers can be employed to improve upon the performance and the limitations associated with a PID controller.

(Refer Slide Time: 48:26)

The slide is titled "Points to ponder" in a red box. Below it, there are two questions in red boxes: "P-1 Why the desired response is a first order filter?" and "P-1 Are there any other method available to overcome the limitations of a PID controller?". Handwritten in black ink are the equations $y_d = r - r e^{-t/\tau_d}$ and $\frac{Y}{R}(s) = \frac{1}{\tau_d s + 1}$, which are circled. The NPTEL logo is in the bottom left corner.

Let us go to the points to ponder; one may ask why the desired response is a first-order filter? As you have seen, we have assumed the desired response to be of the form r minus $r e^{-t/\tau_d}$ within transfer function form gives us y_d upon r as 1 upon $\tau_d s + 1$. So, we have got a first-order filter response from the closed loop system, not necessarily it has to be of first-order filter form; one can employ third-order transfer closed-loop transfer function form or standard transfer function also in the analysis, only that will complicate the analysis, for (()) analysis we have assumed the desired response to be a first-order filter.

Second point might be, are there any other controller or control method available to overcome the limitations of a PID controller? Yes, we have got variants of PID controllers; smith predictor controller, internal model controller, to name a few those can be used to overcome the limitations of a PID controller, thank you.
