Lecture - 20
Continuous Time Markov Chain – 1

(Refer Slide Time: 00:25)

Continuous-time Markov Chain; Sidney's Chapman and Andrey kolmogorov, these are two great mathematicians, who have contributed to Markov chains. Sidney's Chapman is a British mathematician and Kolmogorov, we know that he was a famous Russian mathematician. Now we discussed discrete time Markov Chain were both dead space and the time is discrete earlier we discussed DTCM.

(Refer Slide Time: 00:54)

So, we will discuss now CTMC, Continuous Time Markov Chain where a time is continuous. Time is continuous and state space V is discrete ok. And continuous time Markov chain has many applications for example, that the queuing system, population studies, etcetera where CTMC different type of CTMC gets applications.

(Refer Slide Time: 01:42)

Continuous-time Markov Chain

Consider a random process $\{X(t)\}, t \geq 0$ where state space V is either finite or countable.

$\{X(t)\}$ is called a continuous-time Markov chain if, given time instances $t_1 < t_2 < \dots < t_n < s < s + t$ and integers

$i_1, i_2, \dots, i_n, i, j \in V$, we have

$$P(X(s+t)=j | X(s)=i, X(t_k)=i_k, k=1, 2, \dots, n) = P(X(s+t)=j | X(s)=i)$$

The probability $p_{ij}(s, t) = P(\{X(s+t)=j | X(s)=i\})$ is called the transition probability.

We will start with the definition of continuous time Markov chain. Consider a random process $X(t)$, t greater than or equal to 0 where state space V is either finite or countable basically it is discrete. $X(t)$ is called a continuous time Markov chain if given time

instances t_1 less than t_2 like that $t_1 < t_2 < \dots < t_n$ less than s less than $s + t$. So, we have different instances of time starting with t_1 to s , then $s + t$. And integers i_1, i_2 up to i_n then i_j these are the state values actually belonging to V we have. Now what is the condition for CTMC same as a definition of Markov process that is probability of X of $s + t$ is equal to j .

Given that X_s is equal to i and remaining instances X of t_k is equal to i_k k is equal to one to up to n . So, this is the conditional probability we want to find out this is same as probability of X_{s+t} is equal to j given that X_s is equal to i . So, the conditional probability given that all the previous instances depend only on the current instance. So, that way probability of X_{s+t} is equal to j given that X_s is equal to i .

Now, this probability is important for continuous time Markov chain and this is called this Transition Probability. Step transition probability $p_{ij}(s, t)$ we can write p_{ij} or p_{ij} for simplicity $p_{ij}(s, t)$ is equal to probability that X of $s + t$ is equal to j given that X_s is equal to i is the transition probability.

(Refer Slide Time: 03:46)

Homogenous CTMC

If $p_{ij}(s, t)$ is independent of s but dependent on t , we call the chain to be *homogeneous*. If $\{X(t), t \geq 0\}$ is a homogenous CTMC, then

$$\begin{aligned} p_{ij}(t) &= P(X(s+t) = j | X(s) = i) \\ &= P(X(t) = j | X(0) = i) \\ p_j(t) &= P(X(t) = j) \\ &= \sum_i p_i(0) p_{ij}(t) \end{aligned}$$

$$\begin{aligned} p_{ij}(t) &= P(X(t) = j | X(0) = i) \\ p_j(t) &= \sum_i p_i(0) p_{ij}(t) \end{aligned}$$

Now, we will discuss about homogeneous CTMC suppose $p_{ij}(s, t)$ is independent of s , but dependent on t . We call the same to be homogeneous in that situation we will call the same to be homogeneous. So, that means, $P_{ij}(s, t)$ is a function of t , but not a function of s . If $X(t), t \geq 0$ is a homogenous CTMC then $P_{ij}(t)$ is equal to probability of X_s

plus t is equal to j given that X s is equal to i is same as now because it is homogeneous so what we will get is probability of X t is equal to j given that X 0 is equal to i.

So, that is one important relationship because it is independent of starting point s. So, we can write it as $p_{ij}(t)$ is equal to probability of X t is equal to j given that X 0 is equal to i. Now suppose we have to find out any state probability suppose $p_j(t)$ that is the probability of state j at instant t. So, probability of X t is equal to j. So, how we can find it? Summation over i $p_i(0)$ into $p_{ij}(t)$ because this will give the joint probability and from the joint probability if we sum over i, then we will get the marginal probability so that way we can find out $p_j(t)$. So, $p_j(t)$ is equal to that is first joint probability $p_i(0)$ into $p_{ij}(t)$ and summation over all i. So, this is the their probability at time t.

(Refer Slide Time: 05:48)

Example Independent Increment Process

$$\begin{aligned}
 p_{ij}(s,t) &= P(X(t+s)=j | X(s)=i) \\
 &= \frac{P(X(t+s)=j, X(s)=i)}{P(X(s)=i)} \\
 &= \frac{P(X(s)=i)P(X(t+s)-X(s)=j-i)}{P(X(s)=i)} \\
 &= P(X(t+s)-X(s)=j-i)
 \end{aligned}$$

We will see the transition probability for independent increment process. So, $p_{ij}(s,t)$ is equal to probability of s t plus equal to j even that X s is equal to i. So, that by definition of conditional probability probability of X of t plus s is equal to j and X s is equal to i divided by probability of X s is equal to i. Now this joint probability now can be written as probability of X s is equal to i probability into probability of X of t plus s minus X s is equal to j minus i given that X of s is equal to i.

But because of the independent increment property we write simply probability of X of t plus s minus X s is equal to j minus i. So, this and this get cancelled what we will get is that $p_{ij}(s,t)$ is equal to probability of the increment probability of X of t plus s minus X s

is equal to j minus i . That is the transition probability in the case of independent increment process.

(Refer Slide Time: 07:03)

State-holding Time

When the CTMC enters a state i , the time it spends there before it leaves the state i is called the holding time in the state i . The holding time T_i of the state i is a continuous random variable.

Theorem (a) T_i is memory-less. In other words

$$P(T_i > t + s / T_i > s) = P(T_i > t)$$

(b) $f_{T_i}(t) = \nu_i e^{-\nu_i t}$ where $\nu_i > 0$ is a constant

Proof:(a)

$$P(T_i > s + t / T_i > s) = P(X(u) = i, 0 \leq u \leq s + t / X(u) = i, 0 \leq u \leq s)$$

$$= P(X(u) = i, s < u \leq s + t / X(u) = i, 0 \leq u \leq s)$$

$$= P(X(u) = i, s < u \leq s + t / X(s) = i) \quad (\text{Using Markov property})$$

$$= P(X(u) = i, 0 < u \leq t / X(0) = i) \quad (\text{homogeneity property})$$

$$= P(T_i > t)$$

Thus T_i is memory-less.

We want to study the behaviour of the continuous time Markov chain so for that state holding time is an important concept. When the CTMC enters a state i , the time it spends there before it leaves is called is State Holding Time. So, for a CTMC suppose it will enter a state i and it will remain in this state i for a some random time T_i that time is known as the State Holding Time and it is a continuous random variable because T_i can be any any time.

Now, we have one important theorem which has two parts. Part a says that T_i is memory less, what does it mean that probability that T_i greater than plus s given that T_i greater than s is same as probability of T_i greater than t . So, probability of T_i is greater than t plus s , but given that T_i is greater than s . So, this probability, conditional probabilities same as unconditional probability that T_i is greater than t .

So, that way that it is already T_i is greater than s , that does not have any implication on T_i greater than t plus s so this is the memory less property. And second thing is that T_i is exponentially distributed with parameter ν_i where $\nu_i > 0$ is a constant. We will prove both parts first proof of first part a probability of T_i greater than s plus t given that T_i greater than s . What does it means? Probability that X_u is equal to i up to in during the interval 0 to s plus t , because there is no change in state.

Given that X_u is equal to i during the time 0 to s given that there is no change in state during time 0 to s ; the probability that there will be no change in state during time 0 to s plus t . Now this probability because here u lies between 0 and s plus t and here u lies between 0 and s so this probability will be same as already given that X_u is equal to i for u lying between 0 and s . Therefore, this probability will be same as probability of X_u is equal to i , u lies between s and s plus t given that X_u is equal to i what u lying between 0 and s .

Now, we can use the Markov property. So, that way we will get probability of X_u is equal to i , u lies between s and s plus t ; given that X_s is equal to i so this will get using Markov property ok. So, then what we will get is that probability of X_u is equal to i . Now because of the homogeneity property we can consider u lies between 0 and t given that X_0 is equal to i so this is same as probability of T_i greater than t . So, that way we have used the Markov property once then we used the homogeneity property and proof depth probability of T_i greater than s plus t given that T_i greater than s is same as probability of T_i greater than t , thus T_i is memory less.

(Refer Slide Time: 11:11)

Proof of Part (b)

$$P(\{T_i > t+s\}) = P(\{T_i > t+s\} \cap \{T_i > s\})$$

$$= P(\{T_i > s\})P(\{T_i > t+s\} | \{T_i > s\})$$

$$= P(T_i > s)P(T_i > t)$$

In terms complementary CDF we get,

$$L_{T_i}^c(s+t) = L_{T_i}^c(s)L_{T_i}^c(t)$$

Taking logarithm, $\log_e L_{T_i}^c(s+t) = \log_e L_{T_i}^c(s) + \log_e L_{T_i}^c(t)$

The only function that satisfies the above relationship for arbitrary t and s is

$$\log_e L_{T_i}^c(t) = -\nu_i \times t$$

$$\therefore L_{T_i}^c(t) = e^{-\nu_i t} \quad t \geq 0$$

Handwritten notes:

- $F_X(x) = P(X \leq x)$
- $F_X^c(x) = 1 - F_X(x) = P(X > x)$
- $F_{T_i}(x) = e^{-\nu_i x}$
- $F_{T_i}^c(x) = 1 - F_{T_i}(x) = e^{-\nu_i x}$
- $F_{T_i}(x) = e^{-\nu_i x}$
- $F_{T_i}^c(x) = 1 - F_{T_i}(x) = e^{-\nu_i x}$
- $F_{T_i}(x) = e^{-\nu_i x}$
- $F_{T_i}^c(x) = 1 - F_{T_i}(x) = e^{-\nu_i x}$

We will now prove part b; now let us consider the probability that T_i is greater than t plus s . And that is suppose this is the time axis this is the point t plus s and this is the point suppose s . Now probability that T_i greater than t plus s now T_i greater than t plus s this side is T_i greater than t plus s . So, this right hand side interval is this interval is T_i

greater than $t + s$. Now this interval if I consider that is T_i greater than s so you observe that T_i greater than $t + s$ is the intersection of two interval T_i greater than s and T_i greater than t plus s .

So, that is why probability of T_i greater than $t + s$ it is same as probability that T_i greater than $t + s$ intersection T_i greater than s . So, now, we can write suppose if we take this as the first probability, that is probability of T_i greater than s into probability of T_i greater than $t + s$ given that T_i is greater than s . Now, using the memory less property; so, this probability will be same as probability of T_i greater than t . Therefore, what we get is that probability of T_i greater than $t + s$ in the case of this state holding time is same as probability of T_i greater than s multiplied by probability of T_i greater than t .

So, this quantity is the complementary CDF therefore, in terms of because we know that suppose $F_X(x)$ is probability that X less than equal to small x . Therefore, complementary CDF $F_X^c(x)$ complementary CDF is equal to $1 - F_X(x)$. That is equal to probability that X is greater than small x . So, this is the definition of complementary CDF. And therefore, in terms of complementary CDF we get that $F_{T_i}^c(s + t)$ at point $s + t$ is equal to $F_{T_i}^c(s)$ into $F_{T_i}^c(t)$. So, complementary CDF at point $s + t$ is the product of complementary CDF at instant s into complementary CDF at instant t . Taking the logarithm both sides we will get that $\log F_{T_i}^c(s + t)$ base e is same as $\log F_{T_i}^c(s)$ base e plus $\log F_{T_i}^c(t)$ base e .

So, this is the remarkable result that is the logarithm of a function at the sum of the two arguments is same as logarithm of the function at one argument plus logarithm of the function at the other argument. So, logarithm of this sum is equal to sum of the individual logarithm. The only function that satisfy this relationship for arbitrary t and s is that is $\log F_{T_i}^c(t)$ must be equal to $-\nu_i t$; where ν_i is a positive number. So, that what we will get $F_{T_i}^c(t)$ is equal to $e^{-\nu_i t}$ and this is equal to $1 - F_{T_i}(t)$. And therefore if we take the derivative this quantity is $1 - F_{T_i}(t)$ is equal to $e^{-\nu_i t}$ for t greater than 0 greater than equal to 0.

Now taking the derivative taking derivative with respect to t ; we get what we get what we will get derivative of this is 0 derivative of this is the CDF and right hand side. Similarly we can take the derivative and we will get $F_{T_i}(t)$ is equal to ν_i into $e^{-\nu_i t}$ to the

power minus $\nu_i t$ greater than equal to 0. So, this is the CDF of the state holding time. So, that way we have established their state holding time is memory less and it is distributed at the exponential random variable.

(Refer Slide Time: 16:40)

Structure of a homogeneous CTMC

The operation of a CTMC is as follows:

- (1) Once CTMC enters ~~at~~ state i , it stays at the state for a time $T_i \sim \exp(\nu_i)$.
- (2) Once the CTMC leaves state i , it enters one of the state j with the transition probability $P_{ij}, j \neq i$ such that $\sum_{j \neq i} P_{ij} = 1$.

The two events of leaving the state i and entering the state j are independent because of Markovian assumption

The process of jumping to the state j from state i is like a discrete-time Markov chain and sometimes called an *embedded Markov chain*.

The structure of this embedded MC determines the class property of a CTMC.

After defining the state holding time we can get the structure of a homogeneous CTMC. The operation of a CTMC is as follows, once CTMC enters at state i , enter state i it states at the state for a time T_i which is exponentially distributed that we have established that it will remain in state i for a random time with pdf exponential ν_i . Once the CTMC leaves state i , it enters one of the state j with the transition probability $P_{ij}, j \neq i$ such that summation P_{ij} is equal to one suppose it is in state i now after leaving the state i it will go into other states, but not this state. So, that way it will suppose there is a state j . So, it will go to state j with probability P_{ij} such that sum of all these probabilities where $j \neq i$ must be equal to 1.

So, after leaving this state i it has to go to one of these states j with probability P_{ij} such that summation of P_{ij} is equal to 1. Also due to events of leaving the state i and entering the state j are independent because of the Markovian assumption. Now, this process of jumping to state j from state i is like a discrete time Markov chain and is sometimes called an embedded Markov chain. So, along with a continuous time Markov chain there is always a always an embedded Markov chain. And this structure of the embedded

Markov chain determines the nature of the CTMC. This structure of this embedded Markov chain determines the class property of a CTMC.

(Refer Slide Time: 18:49)

Example Poisson process

Suppose the Poisson process has entered state i at time 0. It will remain in same state until the next arrival with $T_i \sim \exp(\lambda)$. Once an arrival takes place, the state become $i+1$

Thus, for $j \neq i$, $P_{i,j} = \begin{cases} 1, & j = i + 1 \\ 0 & \text{otherwise} \end{cases}$

Example Poisson process, suppose the Poisson process has entered state i at time 0. It will remain in same state until the next arrival which is exponentially distributed. Once an arrival takes place the number of count in the Poisson process will go up by 1 that is this state will become i plus 1. Therefore, for j not equal to i $P_{i,j}$ will be always equal to 0, for j is equal to i plus 1 is equal to 1. So, once it leaves state i , it will go into state i plus one with probability 1 and remaining state with probability 0.

(Refer Slide Time: 19:38)

Short-time Behaviour of the chain at a time interval $(t, t + \Delta t)$

$$\begin{aligned} p_{ii}(\Delta t) &= p(T_i > \Delta t) + o(\Delta t) \\ &= e^{-\nu_i \Delta t} + o(\Delta t) \\ &= 1 - \nu_i \Delta t + o(\Delta t) \end{aligned}$$

$$\lim_{\Delta t \rightarrow 0} \frac{1 - p_{ii}(\Delta t)}{\Delta t} = \nu_i$$

Let us see the Short-Time behaviour of the chain at the time interval $t, t + \Delta t$. This behaviour will determine the dynamics of the CTMC so, that we can get the corresponding equations which govern the behaviour of the CTMC. Now $p_{ii}(\Delta t)$ that is the probability that state holding time T_i is greater than Δt and the; that means, there is no transition during the time t and $t + \Delta t$ plus $o(\Delta t)$.

Suppose this will take account of if there is multiple transition from state i , it has go to state j and it has again come back to state i . So, that probability will be less so that we have been denoted by $o(\Delta t)$. And the therefore, this time we know e to the power $-\nu_i \Delta t$ plus $o(\Delta t)$. and if i expand e to the power $-\nu_i \Delta t$ then i can write it as $1 - \nu_i \Delta t$ plus remaining term I will club with this $o(\Delta t)$ it will be $o(\Delta t)$ only. So, this is the probability that this state will be i after Δt given that it is at state i at time instant 0 . So, that way we can interpret this probability. So, from this what we will get $1 - p_{ii}(\Delta t)$, $1 - p_{ii}(\Delta t)$, $1 - e^{-\nu_i \Delta t}$ divided by Δt equal to ν_i ; that is one important result.

(Refer Slide Time: 21:35)

For $j \neq i$

$$\begin{aligned}
 p_{ij}(\Delta t) &= P(T_i' < \Delta t) \times P_{ij} \\
 &= (1 - e^{-v_i \Delta t}) \times P_{ij} \\
 &= (v_i \Delta t + o(\Delta t)) \times P_{ij} \\
 &= (v_i \Delta t) P_{ij} + o(\Delta t) \quad \text{--- } (v_i P_{ij}) \Delta t + o(\Delta t) \\
 &= q_{ij} \Delta t + o(\Delta t)
 \end{aligned}$$

where $q_{ij} = v_i P_{ij}$ is the probability rate function.

Note that $\sum_{j \neq i} q_{ij} = v_i \sum_{j \neq i} P_{ij} = v_i$ $\sum_{j \neq i} v_{ij} = v_i \sum_{j \neq i} P_{ij} = v_i$

Denoting $v_i = -q_{ii}$, we get $\sum_j q_{ij} = 0$ $\sum_j v_{ij} = 0$

Now, let us see what happened for j not equal to i in that case $p_{ij} \Delta t$. So, what will happen that random time is less than Δt , state holding time is less than Δt that is the probability that T_i is less than Δt , multiplied by. Now there will be a transition from state i to state j so multiplied by P_{ij} this is also capital P . So, this will be equal to again $1 - e^{-v_i \Delta t}$. That is the probability that T_i greater than less than Δt . So, greater than Δt $e^{-v_i \Delta t}$ that we have derived; so, that will list will be $1 - e^{-v_i \Delta t}$ multiplied by P_{ij} . And this quantity again if I expand in terms of that is exponential series the e to the power minus X suppose if I expand then I will get this term, $1 - e^{-v_i \Delta t}$ is $v_i \Delta t + o(\Delta t)$ and whole multiplied by P_{ij} .

So, that way we will get $v_i \Delta t$ multiplied by P_{ij} plus $o(\Delta t)$. Now this quantity actually this v_i into P_{ij} Δt plus $o(\Delta t)$; now this quantity v_i into P_{ij} that is known as the probability rate function so and we denote it by q_{ij} . So, that way q_{ij} into Δt that will become probability so q_{ij} is a probability rate function. And now let us see this sum of the, this q_{ij} values sum of q_{ij} j not equal to i , because there will be no transition to state itself. So, that way this is j not equal to i that is equal to v_i into P_{ij} summation over j not equal to i is equal to that will be now this I know this quantity is equal to 1. So, this will be equal to therefore, this will be equal to v_i because this quantity is equal to 1.

Now, if I denote that ν_i is equal to minus q_{ii} because here I do not consider q_{ii} and sum of these quantity is ν_i . Therefore, if I denote q_{ii} is equal to minus ν_i then I will get summation of q_{ij} over all j is equal to 0. Here we got this summation of q_{ij} not equal to i that is equal to ν_i . Therefore, if I let q_{ii} is equal to minus ν_i then I will get this sum is equal to 0. So, that way this sum of the probability rate function q_{ij} over all state if I consider that must be equal to 0.

(Refer Slide Time: 25:09)

Short-term behaviour lemmas

Lemma 1: $\lim_{\Delta t \rightarrow 0} \frac{1 - P_{ii}(\Delta t)}{\Delta t} = \nu_i$

Lemma 2: $\lim_{\Delta t \rightarrow 0} \frac{P_{ij}(\Delta t)}{\Delta t} = q_{ij}$ where $q_{ij} = \nu_i P_{ij}$

On the basis of the above discussion we present two important lemmas about this short term behaviour of continuous time Markov chain. Lemma 1 states that limit $1 - P_{ii}(\Delta t)$ divided by Δt as Δt tends to 0 is equal to ν_i . So, $1 - P_{ii}(\Delta t)$ is the probability that the chain leaves state i during Δt so this is $1 - P_{ii}(\Delta t)$. And now according to this lemma therefore, the rate of the probability of leaving the state i is equal to ν_i .

Similarly lemma 2 states that limit $P_{ij}(\Delta t)$ divided by Δt as Δt tends to 0 is equal to q_{ij} where q_{ij} is equal to $\nu_i P_{ij}$. So, this P_{ij} is the state transition probability of the embedded Markov chain. So, according to this lemma the rate of the probability of entering this state j from state i is equal to q_{ij} . So, these two lemmas will be very useful in deriving the differential equations governing the evolution of continuous time Markov chains.

(Refer Slide Time: 26:41)

Kolmogorov equations

Chapman Kolmogorov Equation: $p_{ij}(s+t) = \sum_k p_{ik}(s)p_{kj}(t)$

To characterize the transition probabilities dynamically, Kolmogorov backward and forward differential equations are used.

Kolmogorov Backward Equation

$$\begin{aligned}
 p_{ij}(t+\Delta t) &= P(X(t+\Delta t) = j \mid X(0) = i) \\
 &= \sum_k p_{ik}(\Delta t)p_{kj}(t) \\
 &= p_{ii}(\Delta t)p_{ij}(t) + \sum_{k \neq j} p_{ik}(\Delta t)p_{kj}(t) \\
 &= (1 - v_i \Delta t + o(\Delta t))p_{ij}(t) + \sum_{k \neq j} q_{ik} \Delta t p_{kj}(t) \\
 \therefore \lim_{\Delta t \rightarrow 0} \frac{p_{ij}(t+\Delta t) - p_{ij}(t)}{\Delta t} &= -v_i p_{ij}(t) + \sum_{k \neq j} q_{ik} p_{kj}(t) \\
 \therefore p'_{ij}(t) &= -v_i p_{ij}(t) + \sum_{k \neq j} q_{ik} p_{kj}(t)
 \end{aligned}$$

Kolmogorov equations for a CTMC we know this Chapman Kolmogorov equation that is $p_{ij}(s+t)$ that is very obvious. We can write it as summation over $p_{ik}(s)$ over k into $p_{kj}(t)$. So, $p_{ij}(s+t)$ we can write as summation $p_{ik}(s)$ into $p_{kj}(t)$ over k so this is the Chapman Kolmogorov equation. So, first we consider transition to state s and from state s to Kolmogorov equations for CTMC. We can get this Chapman Kolmogorov equation for continuous time Markov chain that is $p_{ij}(s+t)$ is same as summation $p_{ik}(s)$ into $p_{kj}(t)$. So, this is the transition to state k during s and from state k to state j during t .

So, that way we can get the Chapman Kolmogorov equation, but for describing the chain dynamically Kolmogorov forward and backward differential equations are used. First we will derive the Kolmogorov backward differential equation. So, here what we assume is that suppose to this state j at t plus Δt there is transition from state i to some state during Δt and then from those states it will there will be transition during t . So, first this is the time instant Δt we consider and remaining time we will consider later. So, that way it is backward Δt is before t plus Δt . So, that way backward tenure come and now $p_{ij}(t+\Delta t)$ that is equal to probability that X of t plus Δt is equal to j given that X_0 is equal to i . So, $p_{ij}(t+\Delta t)$ we are interested to find then we can find out the derivative.

So, this is same as so from 0 to Δt we can consider and from Δt to t . So, that way this is same as summation $p_{ik}(\Delta t)$ into $p_{kj}(t)$ summation over k . Now here we can

separate out $p_{ii} \Delta t$ into $p_{ij} \Delta t$. First term we have taken out k is equal to i term we have taken out and remaining term suppose k not equal to i . So, this will be summation $p_{ik} \Delta t$ into $p_{kj} \Delta t$. Now I know that $p_{ii} \Delta t$ is equal to one minus $\nu_i \Delta t$ plus $o(\Delta t)$ into $p_{ij} \Delta t$ plus remaining term. Now I know that $p_{ik} \Delta t$ using the lemma two that is equal to $q_{ik} \Delta t$ multiplied by $p_{kj} \Delta t$.

So, that way we have $p_{ij} \Delta t$ plus Δt given by this expression. Now if I take this $p_{ij} \Delta t$ to the left hand side and divided by Δt and consider when Δt tends to 0, then we will get this limit is equal to minus $\nu_i p_{ij} \Delta t$. Because this Δt will come here to the denominator so that way minus ν_i into $p_{ij} \Delta t$ plus q_{ik} into $p_{kj} \Delta t$ because Δt will come to this denominator. And as Δt tends to 0 this will be the derivative of $p_{ij} \Delta t$. So, $p_{ij}' \Delta t$ will be equal to $\nu_i p_{ij} \Delta t$ plus $q_{ik} p_{kj} \Delta t$ k not equal to i .

(Refer Slide Time: 31:03)

Forward Kolmogorov Equation

$$0 \quad \frac{d}{dt} \quad t + \Delta t$$

Consider the figure as shown above. Here,

$$\begin{aligned} p_{ij}(t + \Delta t) &= \sum_k p_{ik}(t) p_{kj}(\Delta t) = p_{ij}(t) p_{jj}(\Delta t) + \sum_{k \neq j} p_{ik}(t) p_{kj}(\Delta t) \\ &= (1 - \nu_j \Delta t + o(\Delta t)) p_{ij}(t) + \sum_{k \neq j} p_{ik}(t) (q_{kj} \Delta t + o(\Delta t)) \end{aligned}$$

$$\therefore p_{ij}'(t) = -\nu_j p_{ij}(t) + \sum_{k \neq j} p_{ik}(t) q_{kj}$$

Writing $q_{jj} = -\nu_j$, we can rewrite the above differential equations as:

$$\text{Forward Kolmogorov Equation } p_{ij}'(t) = \sum_k p_{ik}(t) q_{kj}$$

So, this is the Kolmogorov acquired equation, similarly in the forward equation we consider first time t 0 to t then t to t plus Δt . So, here $p_{ij} \Delta t$ plus Δt will be $p_{ik} \Delta t$ because there will be transition to state k during time t $p_{ik} \Delta t$ into $p_{kj} \Delta t$. So, we can consider here one k is a . So, that will be $p_{ij} \Delta t$ into $p_{jj} \Delta t$ plus summation $p_{ik} \Delta t$ into $p_{kj} \Delta t$ where k not equal to j . Now, this quantity I know and this quantity also I know. So, that way using lemma 1 and lemma 2 I can write this as this quantity as 1 minus $\nu_j \Delta t$ plus $o(\Delta t)$ multiplied by $p_{ij} \Delta t$. So, this this term I am writing using lemma 1.

Similarly, in the here also i use the lemma 2 to get this term $p_{ik} \Delta t$ is equal to $q_{ik} \Delta t + o(\Delta t)$ so that we have written using lemma 2. So, now, what we will do is we will take be $p_{ij} \Delta t$ left hand side and 1 into $p_{ij} \Delta t$ that is equal to $p_{ij} \Delta t$. So, this will take to the left hand side and divided by Δt . So, what we will be left with as Δt tends to 0. What we will get is that? p_{ij}' that is the derivative is equal to minus ν_j into p_{ij} plus summation $p_{ik} q_{kj}$ not equal to j .

So, this is the forward Kolmogorov equation and we can also we earlier defined that q_{jj} is equal to minus ν_j . Then we can write this term also we can club along with this summation we can write p_{ij}' is equal to summation $p_{ik} q_{kj}$ over k this is the Kolmogorov forward equation because here that incremental part we have considered after t . So, that way it is forward equation earlier with derived backward equation.

To Summarise...

- When a CTMC enters a state i , it spends a random duration T_i called the state holding time
 T_i is distributed as $f_{T_i}(t) = \nu_i e^{-\nu_i t} \quad \nu_i > 0$
- Once the CTMC leaves state i , it enters one of the state j with the transition probability $P_{ij}, j \neq i$ such that $\sum_{j \neq i} P_{ij} = 1$.

- Short-time behaviour

$$(1) \lim_{\Delta t \rightarrow 0} \frac{1 - P_{ii}(\Delta t)}{\Delta t} = \nu_i$$

$$(2) \lim_{\Delta t \rightarrow 0} \frac{P_{ij}(\Delta t)}{\Delta t} = q_{ij}$$

Let us summarize the lecture when a CTMC enters a state i , it spins a random duration t_i this is the state holding time and t_i is distributed as exponential distribution that is $f(t_i)$ of t_i is equal to ν_i into e to the power minus $\nu_i t_i$ where ν_i is greater than 0. Once the CTMC leave state i , it enters one of the state j with the transition probability P_{ij} where j not equal to i such that summation P_{ij} over j not equal to i is equal to 1.

So, once the CTMC leaves the state i , it will enter into one of the state j with probability P_{ij} . We also stated two important lemmas regarding the short term behaviour of a

Markov chain these two lemmas are lemma 1 this was the lemma $\lim_{\Delta t \rightarrow 0} \frac{1 - P_{ii}(\Delta t)}{\Delta t} = -q_{ii}$. And the lemma 2 was $\lim_{\Delta t \rightarrow 0} \frac{P_{ij}(\Delta t)}{\Delta t} = q_{ij}$.

To Summarise...

- To characterize the transition probabilities dynamically, Kolmogorov backward and forward differential equations are used.

- **Backward Kolmogorov Equation**

$$p'_{ij}(t) = \sum_k q_{ik} p_{kj}(t)$$

- **Forward Kolmogorov Equation** $p'_{ij}(t) = \sum_k p_{ik}(t) q_{kj}$

THANK YOU

Now, to characterize the transition probabilities dynamically Kolmogorov backward and forward differential equations are used. So, what we got Kolmogorov backward equation that is $p'_{ij}(t) = \sum_k q_{ik} p_{kj}(t)$. So, initially in Δt interval of time it will go to state in state k . So, that is taken care of by q_{ik} into $p_{kj}(t)$. So, that is the backward Kolmogorov equation here from 0 then Δt then $t + \Delta t$.

So, the first transition will take place two different states during duration Δt . And after that from those states to it will go to state j during interval t . So that way this is backward kolmogorov equation similarly forward kolmogorov equation where we have this is 0 then t and $t + \Delta t$. So, that first that there will be a transition to state k at during time t and then from those states there will be transition to state j during the incremental time Δt . So, that way we derived the Kolmogorov forward equation and it is given by $p'_{ij}(t) = \sum_k p_{ik}(t) q_{kj}$ over k .

Thank you.
