Lecture 7
Linear Models of Random Signal

(Refer Slide Time: 00:46)

Let us recall

- ❖ The generalized PSD $S_X(z)$ of a regular WSS process $X(n)$ can be factorized as
$$S_X(z) = \sigma_v^2 H_c(z) H_c(z^{-1})$$
where
 - $H_c(z)$ is a causal minimum-phase transfer function,
 - $H_c(z^{-1})$ is an anti-causal maximum-phase transfer function and
 - σ_v^2 is a constant interpreted as the variance of a white-noise
- ❖ As a consequence, we can model a *regular random process* as an output of a minimum phase linear filter with white noise as input.

```
graph LR; Vn[V(n)] --> Hc[H_c(z)]; Hc --> Xn[X(n)]
```

This lecture will explore some of such models.

Hello students in this lecture I will talk about linear models of random signals. Let us recall the last lecture. These generalized PSD assets that have a regular WSS process X_n can be factorized as $S_X(z) = \sigma_v^2 H_c(z) H_c(z^{-1})$, where $H_c(z)$ there is a causal minimum phase transfer function $H_c(z^{-1})$ is an anti-causal maximum phase transfer function. And σ_v^2 is a constant which can be interpreted as the variance of a white noise.

As a consequence, we can model a regular enough process as an output of a minimum phase linear filter with white noise as input that is this is the white noise V_n appearance z squared this is input to a linear minimum phase filter of transfer function $H_c(z)$ and output is the WSS process X_n this lecture will explore some of such models.

(Refer Slide Time: 02:02)

White noise model

❖ Recall that a white noise process $V(n)$ has zero mean and the autocorrelation function (ACF) given by

$$R_V(m) = \sigma_V^2 \delta(m)$$

❖ Any non-zero mean uncorrelated process becomes zero-mean after the subtraction of the mean. Hence any uncorrelated sequence of RVs can be treated as white noise.

❖ Random data with very small correlation between samples can be modelled as white noise

$$\text{Cov}(X(n), X(m)) = 0 \text{ for } n \neq m$$

The most elementary model is the white noise recall that a white noise process V_n has zero mean so, there is no DC component it is has zero means and the autocorrelation function ACF is given by this R_V of $m = \sigma_V^2 \delta(m)$. So, $\delta(m) = 1$ at $m = 0$ 0 13. Now about any non-zero mean uncorrelated process suppose, the processes non-zero mean, but it is uncorrelated in that case, the process becomes the domain after the subtraction of the mean.

So, therefore, any uncorrelated sequence of random variables also can be treated as white Noise because any non-zero mean uncorrelated process becomes zero mean after the subtraction of the mean and any uncorrelated sequence uncorrelated means that autocorrelation function is delta function that also after subtraction have been it will become zero mean they are pretty to become a white noise.

So, the definition of white noise include zero mean what any non-zero mean uncorrelated random process also can be modelled as white noise. Now, random data with very small correlation between samples can be modelled as white. That means, we have suppose X_n is 1 sample and X_m is another sample and if the covariance between them $= 0$ for m not equal to n then we can write this X_n is white noise.

(Refer Slide Time: 04:03)

Linear Models

- ❖ Spectral factorization theorem enables us to model a regular random process as an output of a minimum phase linear filter with white noise as input

- ❖ In general, $H(z)$ is given by

$$H(z) = \frac{N(z)}{D(z)} = \frac{\sum_{i=0}^q b_i z^{-i}}{1 - \sum_{i=1}^p a_i z^{-i}}$$

- ❖ Different linear models

- If $D(z) = 1$, we have the all-zero MA(q) model.
- If $N(z) = 1$, we have the all-pole AR(p) model
- Otherwise, we have the mixed pole-zero ARMA(p, q) model

Now, let us go to linear models, spectral factorization theorem enable us to model a regular and random processed as an output of a minimum phase linear filter with white noise as input that is V_n is the input to a linear minimum phase system with function is $H_c z$ and extended the output which is WSS process. In general, now, if we consider the transfer function of a core z LTI system minimum phase LTI system and it will have 1 numerator part and denominator part. So, it is a ratio of and that divided by Dz .

Now, this general part we can write this summation i going from 0 to q $b_i z$ to the power $-i$ this is the numerical part. Similarly, denominator part we can write as $1 - \text{summation } i \text{ going from } 1 \text{ to } p \text{ } a_i z \text{ to the power } -i$. So, this is the general transfer function and depending on special situations will have different models. For example, if these are difficult to 1, if this is 1 then H_z will be simply that numerator part will be there.

In that case we have all 0 moving Ma q is model. So, this is a suppose, because there are q terms i equal to i going from 0 to q , therefore, this is a moving average of order q MA q model. When $z = 1$ that means only numerator term is there. When and $z = 1$ then only denominator parties there in that case, we will have poles. So, we have the all pole autoregressive this model is known as the autoregressive or integrated model of order p this is the p parameter.

So, other regressive model of order p and this is because it has only denominator polynomial, so, that will have poles So, this is an all pole model, otherwise the general model will be ARMA autoregressive moving average in terms of parameters p and q model ARMA pq model.

(Refer Slide Time: 06:37)

Linear Models...

- ❖ The ARMA(p,q) models are mathematically described by linear constant-coefficient difference equations.

$$X(n) = \sum_{i=1}^p a_i X(n-i) + \sum_{j=0}^q b_j V(n-j)$$

- ❖ These models are used data in compression, signal prediction, signal understanding, etc
- ❖ In statistics, random-process modelling using difference equations is known as **time series analysis**. It has long been used in signal modelling and forecasting.

Now, in the time domain, this ARMA pq model can be described by linear constant coefficient difference equation. So, this is a different equation in terms of the difference we are getting the equation. Therefore X_n that is the output variable $X_n = \sum_{i=1}^p a_i X(n-i) + \sum_{j=0}^q b_j V(n-j)$ where i going from 1 to P that is the autoregressive part + summation $b_j V$ of $n-j$ where j are they going from 1 to q . So, this is the con linear constant coefficient differential equation model for the ARMA pq process.

P is the number of autoregressive part that mesh it tells about the auto regressive part and it tells about the moving awareness part. These models are very useful, they are used data compression signal predicts on 1 of the very important use of this type of model is forecasting or prediction, signal understanding etcetera in statistics random process modeling, using the Frank's equation is known as time series analysis in statistics for example, in an in a stochastic process stochastic finance for example, we have time series analyzes.

Time series analysis means, we analyze the models, the given by this type of different equations such models has long been used in signal modeling and forecasting. So, their main purpose was earlier it was that is signal modeling and forecasting, but nowadays, this models are used in many signal processing application like speech recognition, etcetera.

(Refer Slide Time: 08:46)

Moving Average, MA (q) model

- ❖ The difference equation model:

$$X(n) = \sum_{i=0}^q b_i V(n-i)$$
- ❖ Thus, impulse response, $h(i) = b_i, i = 0, 1, \dots, q$
 and $H(\omega) = b_0 + b_1 e^{-j\omega} + \dots + b_q e^{-jq\omega}$
- ❖ In terms of z-transform,

$$H(z) = b_0 + b_1 z^{-1} + \dots + b_q z^{-q}$$

Thus, MA(q) is an all-zero model.

So, we will discuss part of moving average of order q . As I have told earlier, this is a FIR filter model. So, there is the white noise in the input and X_n and that is the WSS process, the output differential equation will be $X_n = \sum_{i=0}^q b_i V_{n-i}$ going from 0 to q this is the MA q process. Thus impulse response $h_i = b_i$ how many impulse responses are there are $q + 1$ $i = 0$ 1 up to q . And in the transform domain frequency domain that frequency response $h(\omega)$ is given by $b_0 + b_1 \text{ into } e \text{ to the power } -j\omega + b_2 \text{ into } e \text{ to the power } -j2\omega$ and so on up to $b_q \text{ into } e \text{ to the power } -jq\omega$.

This is the frequency response of the FIR filter the present and make you process in terms of Hz transform will have $H_z = b_0 + b_1 \text{ into } z \text{ to the power } -1 + \text{ up to } b_q \text{ into } z \text{ to the power } -q$. Thus MA q is an all 0 model because there is only that transfer function has only the numerator term. Therefore, it is an all 0 model.

(Refer Slide Time: 10:25)

ACF and PSD of MA(q) process

❖ The autocorrelation function $R_X(m)$

$$\begin{aligned} R_X(m) &= R_V(m) * h(m) * h(-m) \\ &= \sigma_v^2 \delta(m) * h(m) * h(-m) = \sigma_v^2 h(m) * h(-m) \end{aligned}$$

❖ Using the properties of convolution

$$(i) \quad R_X(m) = 0 \quad |m| > q$$

$$(ii) \quad R_X(m) = \sum_{j=0}^{q-m} b_j b_{j+m} \sigma_v^2 \quad 0 \leq m \leq q$$

$$\text{Also, } R_X(-m) = R_X(m)$$

$$\begin{aligned} \therefore R_X(m) &= \sum_{j=0}^{q-|m|} b_j b_{j+|m|} \sigma_v^2 \quad |m| \leq q \\ &= 0 \text{ otherwise} \end{aligned}$$

❖ Power spectral density is given by

$$S_X(\omega) = \sigma_v^2 |H(\omega)|^2 = \left| b_0 + b_1 e^{-j\omega} + \dots + b_q e^{-jq\omega} \right|^2$$

We know that if it is a double exercise process. It is characterized by autocorrelation function. And corresponding power spectral density. We will see what is the ACF autocorrelation function and PSD power spectral density of and MA q process the autocorrelation function R_X of m we know that R_X of $m = R_V m$ convolved with $h(m)$ convolved with h of $-m$ that we derive this relationship while studying that linear system that responsible in linear system to WSS input.

So, they are we established that output autocorrelation function is the convolution of now, in put auto correlation function $h(m)$ and h of $-m$ $h(m)$ is the impulse response of this system. So, now, I know that $R_V m$ because it is the input is white noise $R_V m$ is $\sigma_v^2 \delta(m)$. So, therefore, $R_X m$ will be $\sigma_v^2 \delta(m)$ convolved with $h(m)$ convolved with h of $-m$, but this is $\sigma_v^2 \delta(m)$ any function convolve will get the same function, therefore the this will be $\sigma_v^2 h(m)$ convolved with h of $-m$.

Now, use this properties of convolution. So, you will know because we are to finite the resonant sequence we are convolving therefore, R_X of m will become 0 for $|m|$ greater than q and I put substitute because I know the process RDB parameters. So, if we substitute those and this expression can be simplified to R_X of $m = \sum_{j=0}^{q-m} b_j b_{j+m} \sigma_v^2$ for m lying between 0 and q so, this is the expression for autocorrelation function.

And $R_x(m) = R_x(-m)$ this is the basic property of autocorrelation function of WSS signal therefore, $R_x(m) = R_x(-m)$ therefore generalize upward in this 2 expression we can write $R_x(m) = \sum_{j=0}^{q-m} b_j^2 \sigma_v^2$ where $m \leq q$ otherwise this is the expression for the autocorrelation function away and make you process.

Now, the power spectral density PSD is given by $S_x(\omega)$ that is ACF of $S_x(\omega) = \sigma_v^2 |H(\omega)|^2$, that is, we established that relationship. Now, I know $H(\omega) = b_0 + b_1 e^{-j\omega} + \dots + b_q e^{-jq\omega}$. So therefore, mod of this expression squared into σ_v^2 . So this is the power expression density of a MA q process. So, we got the autocorrelation function given by this expression and power spectral density given by this expression.

(Refer Slide Time: 14:16)

Fitting MA(q) model

- ❖ An FIR filter has zeros only. So if the spectrum has some valleys then MA will fit well.
- ❖ An MA model is always stationary as an FIR filter is always stable.
- ❖ $R_x(m)$ becomes zero for lags greater than q . This is a test for an MA(q) process.
- ❖ $R_x(m)$ is related by a nonlinear relationship with model parameters.

$$R_x(m) = \sum_{j=0}^{q-m} b_j b_{j+m} \sigma_v^2 \quad 0 \leq m \leq q$$

Thus, fitting an MA(q) model is difficult.

Now, how do I fit an MA q model an FIR Filter has zeros only. So, if the spectrum has some valleys then MA will fit well, because if we consider suppose FIR filter it will have 0 and those zeros will give rise to valleys this spectrum. I show an example later on and MA model is always stationary why because FIR filter is always stable and correspondingly, H_m will be also WSS because H_m is double and H_m is the output of this double system and therefore R to a white noise this output will be also stable and stable in the sense of random process it will be stationary.

So therefore, an MA model is always stationary WSS in this case, R_x of m becomes 0 for lags greater than q , this is a test for an MA q process suppose in an MA q process if we plot the autocorrelation function after some lag, this autocorrelation function will drop down to 0 and that point is the order of the an MA q process. Next point is R_x of m is related by a nonlinear relationships.

This is the trouble would be model parameters b parameters the relationship is like this R_x of m = summation $b_j b_{j+m}$ + m sigma v squared j going from 0 to $q - m$. So, this is the relationship between autocorrelation function and the model parameters. Therefore, model parameters are related with autocorrelation function in a nonlinear manner, and finding out these coefficients by solving nonlinear equations, it went suppose that is noisy this will be a complex problem, therefore, fitting an MA q model is difficult.

(Refer Slide Time: 16:45)

Example 1: MA (2) process

❖ The model is given by

$$X(n) = b_0 V(n) + b_1 V(n-1) + b_2 V(n-2)$$

with the parameters b_0, b_1 and b_2

❖ The autocorrelation function is given by

$$R_x(0) = \sigma_x^2 = b_0^2 + b_1^2 + b_2^2$$

$$R_x(-1) = R_x(1) = b_0 b_1 + b_1 b_2$$

$$R_x(-2) = R_x(2) = b_0 b_2$$

$$R_x(m) = 0, |m| > 2$$

❖ The PSD is given by

$$S_x(\omega) = \sigma_v^2 |b_0 + b_1 e^{-j\omega} + b_2 e^{-2j\omega}|^2$$

We will give an example, MA 2 process the model is given by X_n this is the WSS signal = b_0 into V_n + b_1 into V_{n-1} + b_2 into V_{n-2} , therefore 2 is the below q . So 3 parameters are there b_0, b_1 and b_2 , b_n can be considered as a unit variance white noise because any variances is there can be considered in terms of b_0 you know the formula for autocorrelation function of a moment MA process.

So we will get R_x of 0 = sigma x squared = b_0 squared + b_1 squared + b_2 squared R_x of - 1, that will be also equal to R_x of 1 is equal to now it will put the formula R formula here. This

formula, if we put that will get R_x of 1 = b_0 into $b_1 + b_1$ into b_2 similarly, R_x of -2 = R_x of 2 = b_0 into b_2 these are the autocorrelation nonzero autocorrelation values and R_x of m will be equal to 0 for MA 2 the power spectral density will be given by σ_v^2 squared into because this transfer function is $b_0 + b_1 \text{ into } e^{-j\omega} + b_2 \text{ into } e^{-j2\omega}$ mod of debt whole squared.

So, that will be the S_x mod of ω squared, this quantity the mod of S ω squared so this part is the mod of S squared and therefore, this is the expression part a power expression density away moving average process of order 2.

(Refer Slide Time: 18:52)

If we brought this autocorrelation function will get a plug like this auto correlation function after lag row this is 0 1 and 2 after that autocorrelation on sum have become 0 and if we consider the plot of S_x ω versus ω between - π and + π , because it is periodic with PSD to π , so, uniquely defined only between - π and π and we see that there is a valley portion here. So, that is a characteristic of a moving average spectrum ACF when it says after lag 2 PSD shows a Valley region so, this type of if suppose your observe spectrum has this type of behavior then we can model it by an MA q process.

(Refer Slide Time: 19:50)

Autoregressive AR(p) Model

❖ AR(p) model:
$$X(n) = \sum_{i=1}^p a_i X(n-i) + V(n)$$

❖ Transfer function:
$$H(z) = \frac{1}{1 - \sum_{i=1}^p a_i z^{-i}}$$

❖ All-pole model- a_i s are to be properly chosen for the stability of $H(z)$ and hence stationarity of $X(n)$

So, we discussed about moving average process and now let us see what is an autoregressive model autoregressive AR p autoregressive model of order p in this case the filter defining the random process is an IIR filter and all pulled filter that is important. So, this is the V_n is the white noise and X_n is the WSS process AR p model is therefore, $X_n = \text{summation } a_i x \text{ of } n - i \text{ i going from } 1 \text{ to } p + V_1$. So, this present output suppose X_n is consider as a linear combination of past output + this is the input term that is white noise is the input term.

And corresponding transfer function is given by $1 \text{ by } 1 - \text{summation } a_i z \text{ to the power } -i, i \text{ going from } 1 \text{ to } p$. So, this is the transfer function of this IIR filter. Now, in this case it is an IIR filter, so, there are poles this expression will result in poles therefore, this is an all pole model a_i s are to be properly chosen for the stability of H_z and hence stationarity of X_n if z is double then only this X_n sequence will be stationary. So, therefore, we have to select a_i such that the poles of this filter lies inside the unit circle. So, we have discussed what is an AR p model?

(Refer Slide Time: 21:44)

ACF and PSD of an AR(p) process

$$\begin{aligned}
 R_X(m) &= E[X(n)X(n+m)] \\
 &= \sum_{i=1}^p a_i E[X(n+m-i)X(n)] + E[V(n+m)X(n)] \\
 &= \sum_{i=1}^p a_i R_X(m-i) + \sigma_v^2 \delta(m) \\
 \therefore R_X(m) &= \sum_{i=1}^p a_i R_X(m-i) + \sigma_v^2 \delta(m), \forall m \in \mathbb{Z}
 \end{aligned}$$

$$= \sum_{i=1}^p a_i X(n+m-i) + V(n+m)$$

$$E[V(n+m)] \left(\sum_{i=1}^p a_i X(n-i) + V(n) \right)$$

- ❖ A set of linear equations called Yule-Walker equations
- ❖ These equations can be solved to find a_i 's
- ❖ PSD

$$S_X(\omega) = \frac{\sigma_v^2}{|1 - \sum_{i=1}^p a_i e^{-j\omega i}|^2}$$

Now, let us see what is ACF autocorrelation function and PSD of an AR p process. We have to find the ACF autocorrelation function and the power spectral density PSD of an AR p process. We know that $R_X(m)$ is autocorrelation at lag $m = E[X(n)X(n+m)]$. Now, $X(n+m)$ can be considered in terms of its previous output. That way, $X(n+m)$ we are writing is $X(n+m) = \sum_{i=1}^p a_i X(n+m-i) + V(n+m)$ going from 1 to p.

So, in this model we are putting here and then we are taking the expression inside. So, we will get $\sum_{i=1}^p a_i E[X(n+m-i)X(n)] + E[V(n+m)X(n)]$. Now, this term, because of the WSS process, therefore, this quantity will depend only on the lag $n+m-i-n$ that will be simply equal to $m-i$. So, $\sum_{i=1}^p a_i R_X(m-i) + E[V(n+m)X(n)]$. So, $R_X(m) = \sum_{i=1}^p a_i R_X(m-i) + E[V(n+m)X(n)]$ going from 1 to p. Now, this quantity expected value of $V(n+m)X(n)$ that will give us this expression $\sigma_v^2 \delta(m)$.

How because $E[V(n+m)X(n)]$ we can write as $\sum_{i=1}^p a_i E[X(n-i)X(n)] + E[V(n+m)X(n)]$ going from 1 to p. Now, these are the past signals and this is the future input. So, they are uncorrelated because this expression will depend on the previous inputs and will not depend on these inputs. Therefore, this and this expression will be uncorrelated and here $E[V(n+m)X(n)]$ will be uncorrelated but there will be a finite value that varies corresponding to $m=0$.

Therefore, this expression $E[V(n+m)V(n)]$ can be written as $\sigma_v^2 \delta(m)$. Because when $m = 0$ there will be a value $E[V(n)V(n)]$ that is your $V(n)$ into $V(n)$, that way σ_v^2 will come otherwise it will become 0. Therefore, we have now that $R_x(m) = \sum_{i=1}^p a_i R_x(m-i) + \sigma_v^2 \delta(m)$ all this previous autocorrelation value + $\sigma_v^2 \delta(m)$ this is the equation this is for all in this are values of m .

So, that we get a set of linear equations in terms of the autocorrelation function. This set of linear equations are known as Yule-Walker equations and they can be solved to find out the values of a_i now how to find out the power spectral density $S_x(\omega) = \sigma_v^2 / |1 - \sum_{i=1}^p a_i e^{-j\omega i}|^2$ and depressed substitute a mod of $H(\omega)$ squared we will get σ_v^2 squared divided by mod of $1 - \sum_{i=1}^p a_i e^{-j\omega i}$ to the power $-j\omega i$, i going from 1 to p whole squared mod of this quantity whole squared.

So, this is the power spectral density of the AR p process. So, this is the denominator term because it is an all pole filter these are the filter coefficients So, that we now will get this expression mod of $1 - \sum_{i=1}^p a_i e^{-j\omega i}$ to the power $-j\omega i$, i going from 1 to p whole squared so, we see what is the autocorrelation functions and how they are related with the model parameters and our power spectral density is related with the model parameters.

(Refer Slide Time: 27:06)

Fitting AR(p) model

- ❖ All-pole model. If the PSD has sharp peaks, then AR(p) will fit well.
- ❖ $R_x(m)$ is related with model parameters in terms of Yule Walker equations

$$R_x(m) = \sum_{i=1}^p a_i R_x(m-i) + \sigma_v^2 \delta(m) \quad \forall m \in \mathbb{Z}$$

Thus, fitting an AR(p) model is easy.

Fitting an AR p model, because AR p model is an all pole model, if PSD has peaks, then AR p model will fit it well, $R_x(m)$ is related with model parameters in terms of Yule Walker

equations. So that also we know this is a linear setup equation there for solving this set of equations is AR p thus fitting an AR p model is EV we will consider 1 example AR 1 process.

(Refer Slide Time: 27:40)

Example 2: AR(1) process

$$X(n) = a_1 X(n-1) + V(n)$$

$$H(z) = \frac{1}{1 - a_1 z^{-1}}$$

❖ Yule-walker equations

$$R_X(m) = a_1 R_X(m-1) + \sigma_v^2 \delta(m), \forall m \in \mathbb{Z}$$

$$\therefore R_X(0) = a_1 R_X(-1) + \sigma_v^2 \quad (1)$$

and

$$R_X(1) = a_1 R_X(0) \quad (2)$$

❖ From (1) and (2) we get

$$a_1 = \frac{R_X(1)}{R_X(0)} \quad \text{and} \quad \sigma_v^2 = \sigma_X^2 (1 - a_1^2)$$

❖ After some algebra, we get

$$R_X(m) = \frac{a_1^{|m|} \sigma_v^2}{1 - a_1^2}$$

This dependency equation is $X_n = a_1 X_{n-1} + V_n$. And corresponding, H_z will be $= 1$ by $1 - a_1$ into z inverse. So this is the only 1 pole is there at $z = a_1$. Yule walker equation if we substitute $p = 1$ in the Yule Walker equation will get the Yule Walker equation that is R_X of m will be $= a_1$ into R_X of $n - 1$ + σ_v^2 squared into δ , we know this expression R_X of $m =$ this from this might p is 1 therefore, only 1 term will be there and this term will be there.

So, that way R_X of $m = a_1$ times R_X of $n - 1$ + σ_v^2 squared into δ m for all m belonging to z set of integers and R_X of 0 therefore, if we put $m = 0$ that will be $= R_X$ of -1 + σ_v^2 squared and second equation R_X of 1 $= a_1$ into R_X of 0. That is the when we put $m = 1$ when $m = 0$ we get this but we know that $R_X - 1$ is also $= R_X$ of 1 from 1 and 2 will get $a_1 = R_X$ of 1 divided by R_X of 0 this is the value of AR coefficient a_1 then $a_1 = R_X$ of 1 divided by R_X of 0.

And we can determine also see that relation, we have to find out what is the variance of white noise suppose that is σ_v^2 squared will be equal to σ_x^2 squared into $1 - a_i^2$ squared. So this is 1 equation. This is another equation to unknown there a_1 and σ_v^2 squared. So a_1 σ_v^2 squared can be found out from R_X 1 and R_X 0. So we have found out what is a_1 that $= R_X$ of 1 divided by R_X of 0 and σ_v^2 squared this σ_v^2 squared $= \sigma_x^2$ squared into $1 -$

a_1 squared. After now we have a differential equation, R_x of $m = a_1 R_x$ of $m - 1 + \sigma_v^2$ squared into Δm this is the differential equation.

And I know what is R_x of 0 suppose it is related with σ_v^2 , that the sum is R_x of 0 $\sigma_v^2 = R$ of 0 into $1 - a_1^2$, therefore R_x of 0 = σ_v^2 divided by $1 - a_1^2$. And if I sold this set of differentiation with the initial condition, and we will find out this solution for the autocorrelation function. So, it will be exponentially decreasing function. So, we can plot this autocorrelation function.

(Refer Slide Time: 31:09)

This is the plot of autocorrelation function for different will have m so, it will gradually going down and similarly this power spectral density in this case, pole is z at that is real axis pole is a real number. Therefore, it will have a sharp pickup originally 0 frequently on the this is the power spectral density plot of a typical AR 1 process and this is the typical autocorrelation plot.

(Refer Slide Time: 31:45)

Markov process model for AR(1) process

❖ Consider the AR(1) model

$$X(n) = a_1 X(n-1) + V(n)$$

$$P(X(n) = x / X(n-i) = x_i, i = 1, 2, \dots)$$

$$= P(V(n) = x - a_1 x_1)$$

$$= P(X(n) = x / X(n-1) = x_1)$$

❖ Thus AR(1) is a Markov model and this interpretation has wide applications.

Now, 1 important interpretation of AR process as the Markov process consider the AR 1 process that is $X_n = a_1 x_{n-1} + V_n$ then probability of $X_n = z$ given suppose $X_{n-i} = x_i, i = 1, 2$ etcetera this all the term given then I know that is probability of $X_n = x$ that the same X_{n-1} will be equal to we can add the probability of $V_n = x - a_1 x_1$ because when I put x_{n-1} that will be $= x_1$.

So, if $x_{n-1} = x_1$ $x_{n-1} = x_1$ then what will be V_n . V_n will be $X_n = x$ therefore V_n will be $= x - a_1 x_1$. So, this conditional probability is same as probability of $V_n = x - a_1 x_1$ and the same result will get if you only consider 1 term probability of $X_n = x$ given that $x_{n-1} = x_1$ and then also will get the same expression. Therefore, this conditional probability given all the previous value is same as the conditional probability given the immediate past $x_{n-1} = x_1$. So, same model is known as the Markov model that AR 1 is a Markov model and this interpretation has wide application. Later on we will see.

Summary

- ❖ A general ARMA(p,q) model is mathematically described by linear constant-coefficient difference equations.

$$X(n) = \sum_{i=1}^p a_i X(n-i) + \sum_{j=0}^q b_j V(n-j)$$

- ❖ An MA(q) model is given by

$$X(n) = \sum_{i=0}^q b_i V(n-i)$$

- ❖ The ACF $R_X(m)$ of an MA(q) process is related by a nonlinear relationship with model parameters.

$$R_X(m) = \sum_{j=0}^{q-m} b_j b_{j+m} \sigma_v^2 \quad 0 \leq m \leq q$$

- ❖ $R_X(m)$ for an MA(q) process vanishes after lag q.

Let us summarize the lecture is general ARMA of pq model is mathematically described by a linear constant coefficient difference equation. So, $X_n = \sum_{i=1}^p a_i x_{n-i} + \sum_{j=0}^q b_j V_{n-j}$. This is generalize expression for ARMA of p, q model, which we derived from this spectral patriotism theorem. Then we considered moving MR 1 process which has only numerator part in the filter.

So an MA q model is given by $X_n = \sum_{i=0}^q b_i V_{n-i}$ this is the model for the MA q process moving a whereas process of order q the ACF autocorrelation function $R_X(m)$ moving MA q process is related by a nonlinear relationship with the model parameters, what are the model parameters, this $b_i V$ are the model parameters, they are related with the autocorrelation function we can find out them from the autocorrelation function.

That is $R_X(m)$ is given by $\sum_{j=0}^{q-m} b_j b_{j+m} \sigma_v^2$ where m lies between 0 and q and $R_X(m)$ for n and MA q process when i says after like q this is these 2 factors are important.

Summary ...

- ❖ The all-pole AR(p) model is given by

$$X(n) = \sum_{i=1}^p a_i X(n-i) + V(n)$$

- ❖ The ACF and the AR parameters are related by

$$R_x(m) = \sum_{i=1}^p a_i R_x(m-i) + \sigma_v^2 \delta(m), \forall m \in \mathbb{Z} \quad \leftarrow \text{Yule Walker Equation}$$

The PSD is given by

$$S_x(\omega) = \frac{\sigma_v^2}{|H(\omega)|^2} = \frac{\sigma_v^2}{|1 - \sum_{i=1}^p a_i e^{-j\omega i}|^2}$$

- ❖ Simplest AR model is the AR(1) model given by

$$X(n) = a_1 X(n-1) + V(n), |a_1| < 1$$

- ❖ AR(1) is a Markov process.

And this is a nonlinear relationship because of depth putting it putting in MA q model is difficult. The All-Pole model AR p is given by AR p autoregressive process of order p is given by $X_n = \sum_{i=1}^p a_i X_{n-i} + V_n$. So, here i in the filter model only denominator part will be there that why it is an all-pole model the ACF and the AR parameters a_i already AR parameters auto regression parameters this ACF and the AR parameters are related by the Yule Walker equation these are the Yule Walker equation.

Because for different values of m will get a set of equation with a different equation in terms of the autocorrelation function. So, that we will have a number of because then we can suppose there are p parameters are there on 1 more parameter is σ_v^2 squared to solve them, we can consider p + 1 equation out of them and we can find out those value. And solving those equations are not difficult.

Because they are linear equations and the PSD is given by this S_x of $\omega = \frac{\sigma_v^2}{|H(\omega)|^2} = \frac{\sigma_v^2}{|1 - \sum_{i=1}^p a_i e^{-j\omega i}|^2}$ simplest AR model we discussed that is AR 1 model which is given by $X_n = a_1 X_{n-1} + V_n$, where mod of $a_1 = |a_1| < 1$ that is this requirement for stationarity AR 1 is a Markov process that also we established. Thank you.
