Lecture-20
Reading-II

Hello and welcome to the course Introduction to Advanced Cognitive Processes. I am Ark Verma from IIT Kanpur and we have been talking about language in the last week or so. We have talked about aspects of reading in the last lecture and I will just try and take that discussion a little bit further by involving some of the cognitive processes that are there in reading what are the aspects of scripts that, you need to keep in mind.

And a little bit about difficulties in reading which is again covered under section referring to dyslexia. So, let us begin rather quickly.

(Refer Slide Time: 00:49)

Cognitive Processes in Reading

- Written scripts differ & so do their reading behavior.
 - E.g. scripts have *idiosyncratic features*. *Alphabetic* scripts differ from *pictographic* or *logographic* scripts.
- In an alphabetic script:
 - A collection of letters.
 - Individual letters or bigrams or trigrams correspond to individual speech sounds or *phonemes*.
- In a pictographic script:
 - Each character or symbol may look like the concepts it represents.

So, what kind of cognitive processes might be intervening reading you know reading scripts differ. So, script of Hindi or script of English is very different from the script of Hebrew or Prussian or for that matter Chinese or Japanese.

So, different scripts have basically things called idiosyncratic features and these idiosyncratic features are those unique aspects that each scripts has. And the reader of each of these scripts have to be well versed with have to be familiarized with these

idiosyncratic features in order to master reading using that particular script ok. Say for example, alphabetic scripts are slightly different pictographic scripts are different and logographic scripts are different.

So, in alphabetic scripts we typically English is an alphabetic script there is a collection of letters each letters or groups of letters or bigrams or trigrams basically stand for or correspond to individual speech sounds or phonemes. And basically each because each letter is a phoneme you combine letters as you combine sounds and you create words out of that a pictographic script is one.

Suppose for example,; that means, is wherein each character or symbol may look like the concepts that it is trying to convey. So, for example, each letter if you are say for example, in a particular script if you want to depict how you know you want to talk about a tree it is quite probable that your description that your symbol for tree looks or resembles the tree in some form ok.

(Refer Slide Time: 02:23)

- In logographic scripts:
 - Each symbol maps onto a unit of meaning, such as a morpheme or a word & symbols don't need to resemble what they represent.
- Chinese, however may be described as a *morpho-syllabic writing system*:
 - Each symbol represents both a morpheme and a syllable.
 - Characters consist of two elements:
 - *a semantic radical*: cues meaning.
 - *Phonological radical*: cues pronunciation.

So, that is one and there are logographic scripts in logographic scripts what happens is that each symbol will map onto a unit of meaning such as morpheme or a word and symbols do not really need to resemble what they are representing unlike the pictographic scripts. So, these are the three broad varieties of scripts that you can talk about. Now I have very you know interesting example in Chinese; Chinese have has been described by people as morpho syllabic writing system.

What does a morpho syllabic writing system? It is nothing really to be afraid of or very complicated here each symbol letter each symbol will represent both a morpheme a part of the word and a syllable a part of the phonological word. So, characters consists of two elements one is a semantic radical which will tell you something about the meaning of what it is representing and phonological radical that will tell you about how this has to be pronounced.

(Refer Slide Time: 03:19)

- Still there are similarities:
 - Both scripts lead to automatic activation of phonological codes.
 - E.g. heterophonic homographs take longer to read. *Wind* has two sounds, with the same form.
 - Words with inconsistent pronunciation patterns take longer to read. E.g. *have, save*.
 - Heterographic homophones take longer to correctly identify. *Meet* takes longer to reject as "food".
 - *Pseudo homophones* take longer to reject. *Brane* take longer to reject as a non-word.

So, in that sense because there are morphemic and syllabic aspects Chinese is referred to as morpho syllabic scripts; however, there are some similarities with the morphological with the Chinese scripts with other scripts for example, both kind of scripts will lead to automatic activation of phonological codes. So, there is the phonological radical it will automatically help you generate a pronunciation for whatever you are reading.

So, heterophonic homographs you know things that sound different, but written in the same way. So, suppose for example wind has two sounds with the same form. So, wind basically can be read as wind or it can be read as wind. So, it is homographic features the same set of words has to sound associated to the wind and wind.

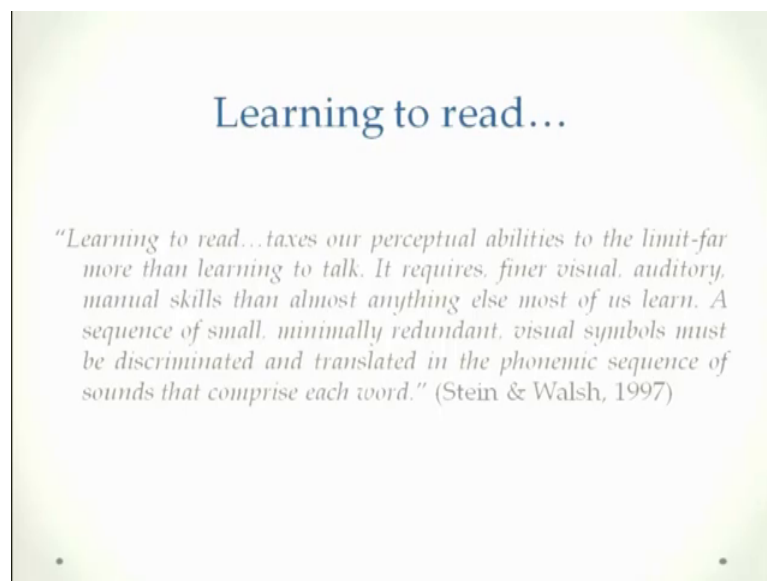

So, these kinds of things will take longer to read in both alphabetical scripts and scripts like Chinese. Also words with inconsistent pronunciations would take bit longer. So, suppose h a v e is have, but s a v e is not save its save. So, there is inconsistency in

pronunciation coming which; obviously, will slow the reader down while reading aloud other things are heterographic homophones.

So, things that are written differently, but are sounding exactly the same meet takes longer to reject as food because m e e t stands for meeting somebody, but it also sounds like m e a t which is food. So, if you kind of ask somebody you present this word meat and ask them the food or not it might take them a little bit longer to reject meat as a food item

Also another script pseudo homophones are difficult to reject they take a long time to reject for example, the word b r a n e which basically resembles the sounds of brain b r a i n we will take a little bit longer to reject. All of these kind of effects are very similarly happening across Chinese scripts like English as well.

(Refer Slide Time: 05:16)

So, this is again some similarity between the two kind of scripts because we are just trying to talk about sounds and everything let us talk a little bit about building block of reading.

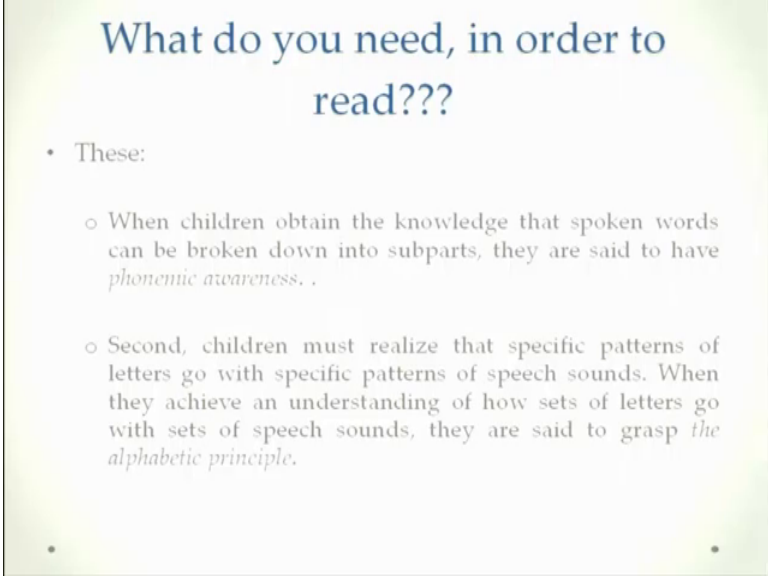

So learning to read again I am just borrowing a quote from Stein and Walsh from (Refer Time: 05:30) book learning to read taxes our perceptual abilities to the limit far more than learning to talk. Because again if you remember the way I began this discussion on reading is that reading is fairly unnatural it requires finer visual auditory manual skills

than anything that almost anything that we learn, it is probably one of the most complicated task that we have to you know we have to learn to master. Also a sequence of small minimally redundant visual symbols must be discriminated from each other and then translated in the phonemic sequence of sounds that comprise each word.

So, I mean this should help you kind of appreciate how difficult it is you know these are very small symbols you know a b c d e f or [FL] and [FL] and those kind of things these have to be converted into sounds you are just looking at the visual. The visual has to be connected to the sound and the sound has to be connected to the meaning all of this has to be done at a fairly rapid pace you know rather dynamic fashion.

So, in that sense reading is difficult. So, what do you really need to do in order to learn to read at least two things.

(Refer Slide Time: 06:33)

What do you need, in order to read???

- These:
 - When children obtain the knowledge that spoken words can be broken down into subparts, they are said to have *phonemic awareness*.
 - Second, children must realize that specific patterns of letters go with specific patterns of speech sounds. When they achieve an understanding of how sets of letters go with sets of speech sounds, they are said to grasp *the alphabetic principle*.

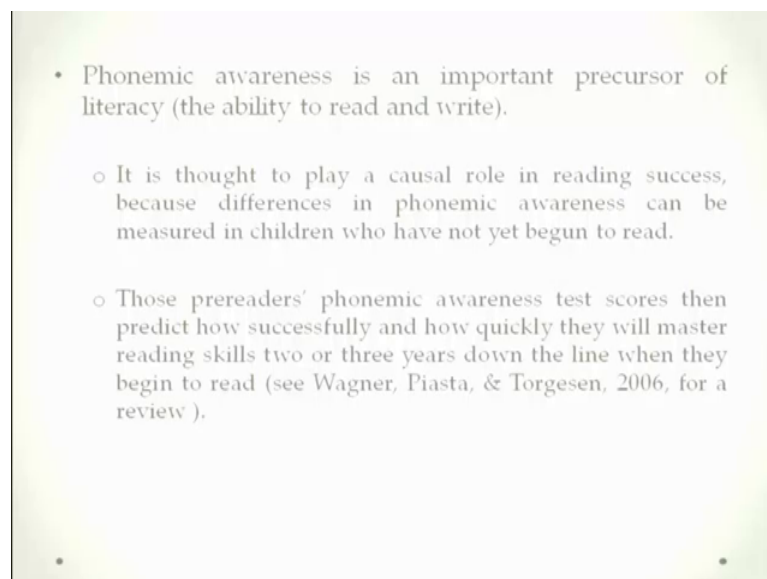

When children are obtaining the knowledge that spoken words can be broken down into subparts they are said to have phonemic awareness. So, something that the child has to learn to master is this aspect of phonemic awareness whatever I am saying can be broken down into sounds and sounds has to have to be represented by you know the basic symbols.

So, this phonemic awareness that you can break things down into sounds is very important. The other thing is that the children must realize that specific patterns of letters go with specific patterns of speech sounds.

So, you have to be able to put together letters together to create sounds and that is also important effect. So, when they achieve this understanding of how you know sets of letters go together to create specific sounds they are said to have grasp what is called a alphabetic principle.

So, one of the two basic abilities that you need to master in order to learn to read is the phonemic awareness the fact that you know spoken words can be broken down into subparts smaller sounds a and the second is that the subparts can be created by a you know putting together particular kinds of specific letters is the alphabetic principle.

(Refer Slide Time: 07:46)

- 
- Phonemic awareness is an important precursor of literacy (the ability to read and write).
 - It is thought to play a causal role in reading success, because differences in phonemic awareness can be measured in children who have not yet begun to read.
 - Those prereaders' phonemic awareness test scores then predict how successfully and how quickly they will master reading skills two or three years down the line when they begin to read (see Wagner, Piasta, & Torgesen, 2006, for a review).

These two things are very important phonemic awareness is supposed to be one of the most important precursors of literacy you know. Unless the child masters this principle of phonemic awareness it is very difficult rather impossible for the child to master reading it is thought to play a causal role in reading success because difference in phonemic awareness have been measured in children and they have basically been correlated with the final ability to read.

So, children who have been found to be very good with phonemic awareness have been found to acquire reading more seamlessly in better way at earlier. Children who have been found to be deficit in phonemic awareness have been basically you know linked with difficulties in acquiring reading.

(Refer Slide Time: 08:27)

- Phonemic awareness can be assessed in a variety of ways, including the *elision*, *sound categorization*, and *blending* tasks (Torgesen et al., 1999), among others, but the best assessments of phonemic awareness involve multiple measures.
 - In the elision task, children are given a word such as *cat* and asked what it would sound like if you got rid of the /k/ sound.
 - Sound categorization involves listening to sets of words, such as *pin*, *bun*, *fun*, and *gun*, and identifying the word "that does not sound like the others" (in this case, *pin*; Torgesen et al., 1999, p. 76).
 - In blending tasks, children hear an onset (word beginning) and a rime (vowel and consonant sound at the end of a syllable), and say what they would sound like when they are put together.

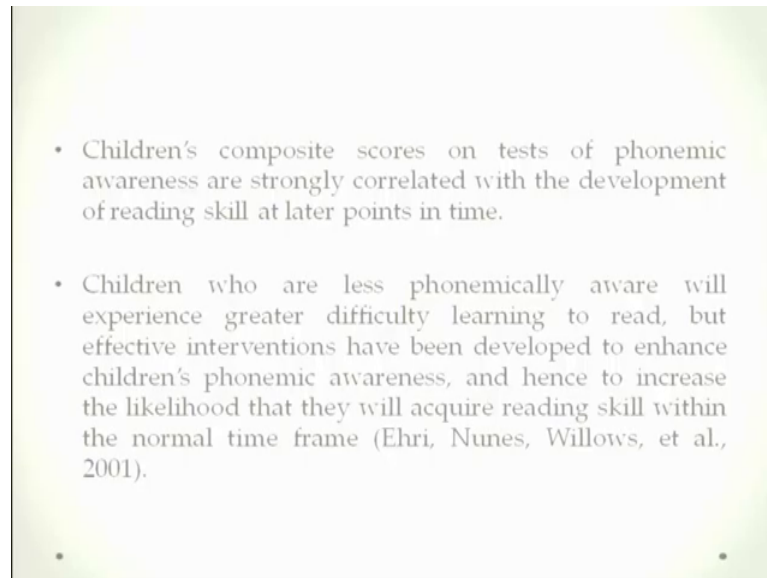

Phonemic awareness and there is a way to measure them phonemic awareness can be assessed in a variety of ways. For example, the elision task in which you give the child a particular sound suppose I asked the child to give cat mat bat hat and then I ask the child to say remove the ka sound and tell me how it sounds.

So, the child should be able to tell me at remove the ba sound then how does this sound the child should be able to tell me at. So, this the elision task different kind of task is sound categorization wherein basically it involves you know listening to sets of words and identifying the word that does not fit suppose I am saying a pin bun fun gun.

So, the child should be able to tell that pin is different from bun fun and gun. Again the idea is that you teaching the child to appreciate how sounds are created, how sounds can be broken down and changed manipulated etcetera. In the blending task again a very similar task to just make an awareness children hear an onset and a rime the beginning of the syllable and the end of the syllable.

And they basically try and see how you know what they will sound like if you would combining two different syllable cap and pat. How do you know if you take the beginning of one end end of one it probably can be made as pat. So, the child needs to be able to break these things down and play with these a little bit so, that the child acquires you know phonemic awareness and masters the basic principle of reading.

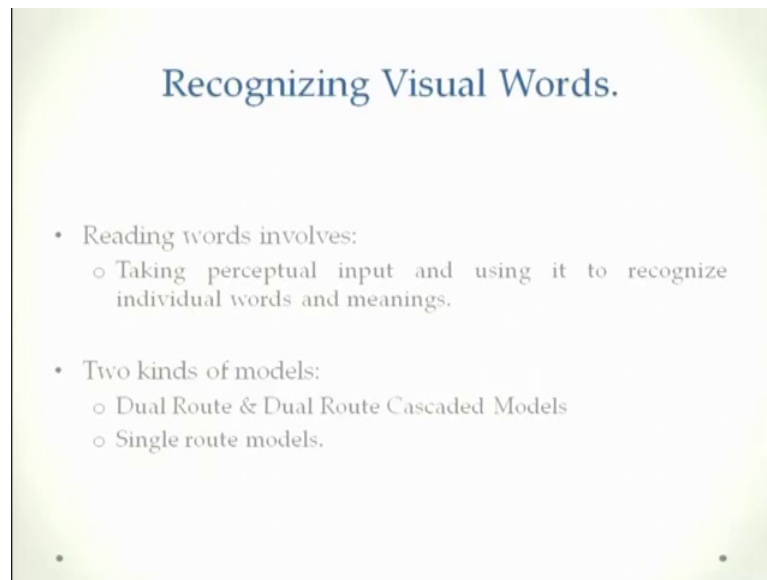

(Refer Slide Time: 09:47)

- 
- Children's composite scores on tests of phonemic awareness are strongly correlated with the development of reading skill at later points in time.
 - Children who are less phonemically aware will experience greater difficulty learning to read, but effective interventions have been developed to enhance children's phonemic awareness, and hence to increase the likelihood that they will acquire reading skill within the normal time frame (Ehri, Nunes, Willows, et al., 2001).

Now, children's composite scores on tests of phonemic awareness using task like I just described; here have been found to be strongly correlated with the development of reading skills at a later point in time.

Also it has been seen that children who are less phonemically aware will experience greater difficult in learning to read and for this reason people have come up with various methods various interventions to develop and enhance the children's phonemic awareness. And hence to increase the likelihood that they will turn into better readers highly skilled readers as time passes by. So, this is little bit about phonemic awareness.

(Refer Slide Time: 10:27)

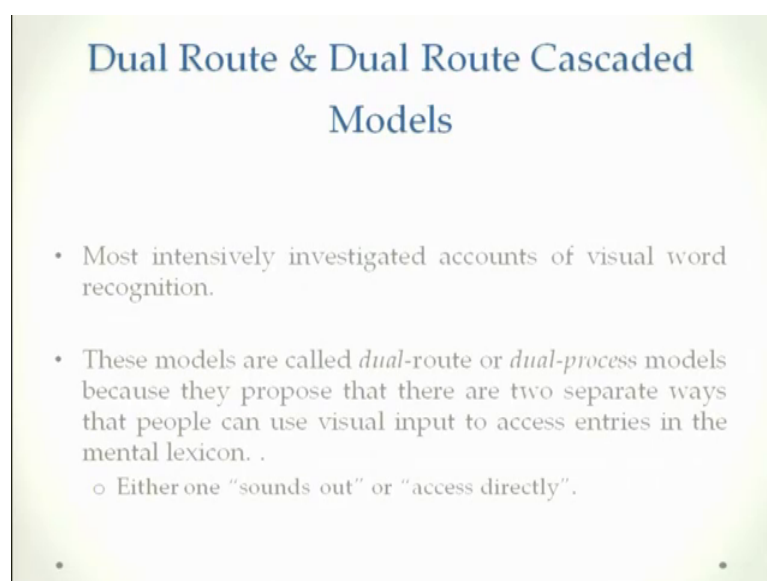

Recognizing Visual Words.

- Reading words involves:
 - Taking perceptual input and using it to recognize individual words and meanings.
- Two kinds of models:
 - Dual Route & Dual Route Cascaded Models
 - Single route models.

Let us now move to recognizing visual words; in the last lecture I was talking to you about reading using eye movements I was mostly talking little bit about how do you read longer sentences I am just in this lectures spending some time on reading individual words. So, individual word reading basically involves taking a perceptual input and using it to recognise a word and meaning.

There are two kinds of models dual route models and single route models.

(Refer Slide Time: 10:58)

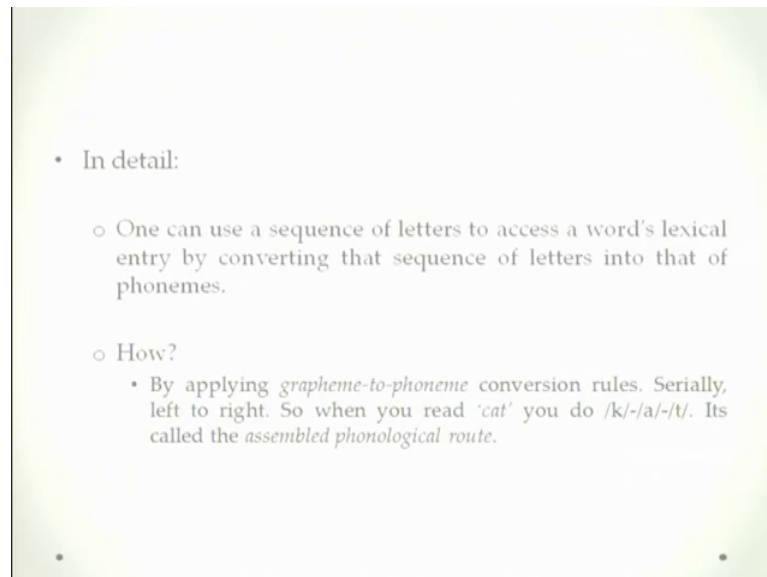

Dual Route & Dual Route Cascaded Models

- Most intensively investigated accounts of visual word recognition.
- These models are called *dual-route* or *dual-process* models because they propose that there are two separate ways that people can use visual input to access entries in the mental lexicon. .
 - Either one “sounds out” or “access directly”.

The dual route models basically I have been one of the most investigated accounts of visual world recognition. And these models are called dual route or dual process models because they propose that at least there are two ways of wherein reading can occur. The first way is the direct access way and the second way is the sounding out way.

(Refer Slide Time: 11:19)

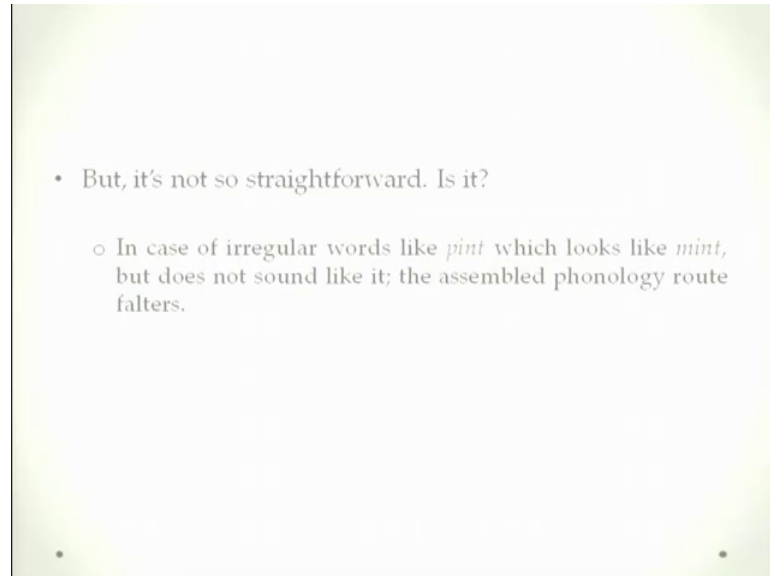

I will just describe this in a little bit more. So, idea is if you are actually looking at you know bunch of letters put together as a word; there are two ways that you can read it. The first is that you can use this in sequence of letters; so, access a words lexical entry by converting that sequence of letters into that of phonemes.

Suppose you are reading b a t bat you have to come up with the sound of what b stands for and what a stands for and what t stands for link all of this together you have sounded this out now you know that b a t means bat; so, it is bat.

So, this is one of the ways of doing this conversion that I was talking about is referred to as grapheme to phoneme conversion; grapheme is the visual symbol phoneme is the auditory symbol. So, you have to convert the visual symbol into the auditory symbol in order to understand the meaning of the word that is the g-p-c conversion and when you are reading using the g-p-c conversion route you are basically using what it is referred to as the assembled phonology route.

So, assembled phonology route is basically when you sounding out each letter sequence in the word and then constructing a sound based representation.

(Refer Slide Time: 12:31)

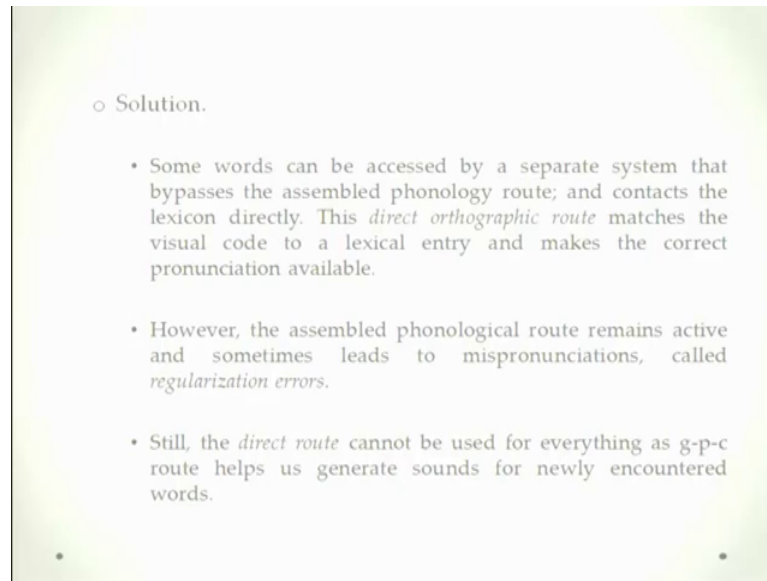

However it is not really straightforward you know suppose for example, you are reading irregular word like pint you know p i n t its very probable that you know somebody has not read this word earlier might make a mistake and read this as pint. Because you know you have you probably will have more familiarity with the word mint because mint is something that you kind of you know come across more often.

So, if you come across mint and then you are kind of a reading this word pint you not really being able to you will not really be successful in coming to the correct pronunciation if you are using the assembled phonology route. So, how do you do it because the assembled phonology route is leading it to problems. Suppose and it will lead you to problems in words like bouquet for example, b o u q u e t bouquet basically you know you say it as bouquet, but if you go with the phonology route you probably say as bouquet or something like that ok.

So, it is fairly evident that the assembled phonology route might lead you to certain mistakes. So, what is the solution?

(Refer Slide Time: 13:40)

o Solution.

- Some words can be accessed by a separate system that bypasses the assembled phonology route; and contacts the lexicon directly. This *direct orthographic route* matches the visual code to a lexical entry and makes the correct pronunciation available.
- However, the assembled phonological route remains active and sometimes leads to mispronunciations, called *regularization errors*.
- Still, the *direct route* cannot be used for everything as g-p-c route helps us generate sounds for newly encountered words.

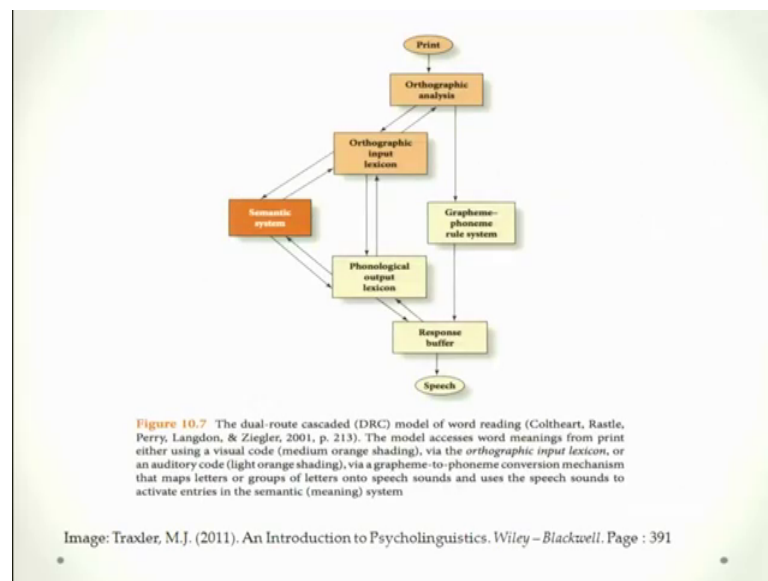

There is a solution and the solution is that some words need to be accessed, some words which are irregular which are not really following the grapheme to phoneme conversion consistency.

They might be accessed directly; you know you have to memorize them you have to remember that there is an exception rule being applied here. And this exceptional rule the invocation of this exceptional rule is referred to as the direct orthographic route. So, the direct orthographic route matches the visual code to a lexical entry that is in your brain and it is that this matching will make the correct pronunciation available to you. You are not going by sounding a sequence of the letters what you are doing is you are reading this you know that you know this you check whether you know this word already and you come up with a direct pronunciation already.

So, also it does not really mean that you know the symbol for the assembled phonology route becomes inactive the assembled phonology route also becomes active and sometimes it would lead you to mispronunciations which are referred to as regularization errors. Suppose if I start saying I start reading p i n t s pint this is a regularization error I should remember that you know if this basically p i n t as stands for pint and that we will be the access to direct route, but sometimes I will make this mistake and I will read p i n t as pint that is where I am committing the regularization error.

Still the direct route cannot be used for everything as g-p-c route generally helps us generate sounds for newly encountered words. You know direct route is accessible only for the points that you know this word if you have not seen this word earlier. If you are not aware of this word reads like then you will anyways end up using the grapheme to phoneme conversion the assembled phonology route and that is why the route is also very important.

(Refer Slide Time: 15:26)

This is how the direct dual route cascaded model looks like; you will see that there is a direct connection from orthographic analysis to a response buffer which is the grapheme phoneme rule system. And then there is the orthographic input lexicon and the phonological input lexicon again you will see how these things are connected.

More important is; however, I have described already how this model really works. If you really noticed the g-p-c route if you look back at this figure the g-p-c route postulates serial activation code for letters.

(Refer Slide Time: 15:52)

- Did you notice?
 - The g-p-c route postulates serial activation of phonological codes for letters.
 - Evidence?
 - DRC predicts longer reading times for *irregular words* like *pint*, *colonel* etc. If g-p-c conversion happened serially, left to right irregularity at the beginning should cost more than at the end. Indeed, *choir* is harder to read than *benign*.
 - Not all good. DRC predicts words with earlier *visual uniqueness points* should be read more quickly than those with later. As in "*dwarf*" should be read slower than "*carpet*". NOT found.

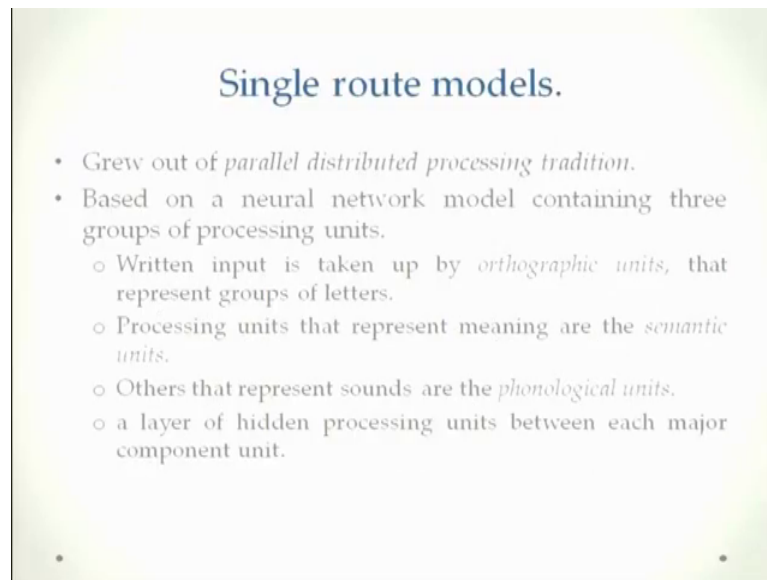

So, g-p-c route basically is going to tell you that you know you activate first letter first second letter and third letter this is the serial allocation that that needs to happen. So, is there any evidence of these are we doing it in parallel or are we doing it in serial. So, there is some evidence for this.

So, dual route model basically predicts that they will be larger reading time for irregular words like *pint* and *colonel* etcetera and suppose if g-p-c conversion was happening serially left to right irregularity in a left to right fashion; irregularity at the beginning of the word will should cost more or will cost more than irregularity at the end.

And if you really look at the experimental results that are available you will find that if there is irregularity at the beginning of the word, you generally take more time in reading that word it kind of can act as an evidence of saying that this dual route this assembled phonology thing is happening serially and it is happening from left to right depending on the direction of text that you are reading that is there.

But if it does not really apply across the board for some cases DRC predicts that you know words with earlier visual uniqueness points. Suppose for example, the words like *dwarf* should be read slower than words like *carpet*, but this has not really been found *dwarf* is also read as fast as *carpet* and then this kind of thing you know it is in a bit of a problem again I will just enumerating some evidence related to what reading experiments have shown and again this is something that is ongoing.

(Refer Slide Time: 17:39)

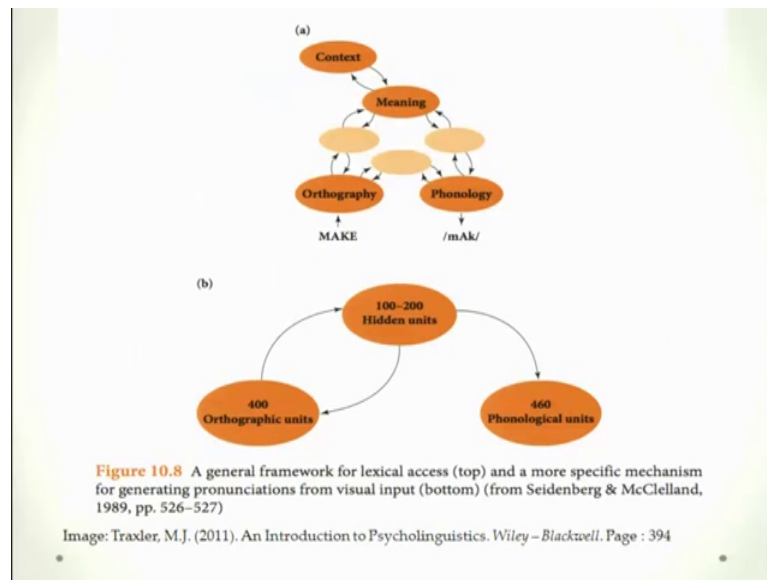

The slide is titled "Single route models." and contains the following text:

- Grew out of *parallel distributed processing tradition*.
- Based on a neural network model containing three groups of processing units.
 - Written input is taken up by *orthographic units*, that represent groups of letters.
 - Processing units that represent meaning are the *semantic units*.
 - Others that represent sounds are the *phonological units*.
 - a layer of hidden processing units between each major component unit.

So, a lot of evidence are kind of sometimes contradicted. So, we talked about how reading would happen, we talked about this model of reading and this was the dual route model. Let us look at one of the single route models the single route models again it kind of borrows from the parallel distributed processing tradition McClelland and Rumelhart.

And what do you say is reading really happens in just one process, what they have his they have a neural network based model has a particular components, do the orthographic processing where in the visual analysis is done, it has components that represent meaning which is the semantic units and then it has components which have the phonological. So, they had orthography components meaning related semantic components and phonology related sound based components.

(Refer Slide Time: 18:26)

And therein there is a hidden of layer of hidden units and this you know contribution between this between hidden units is basically what achieves this process of reading.

So, if you can look at that figure a here the context is also playing a role meaning is there orthography phonology are also interacting.

(Refer Slide Time: 18:43)

- Visual input leads to activity in the orthographic unit, which leads to activity in hidden units which govern the activity in the phonological units; leading to naming response.
- Every word is represented as a distributed pattern of activation across the entire network.
- “learning involves modifying the weights to through experience in reading aloud.”
- Further, each processing unit is connected to others, so that when one unit is activated it can influence the activation of other units.
- To start with, connection weights are randomized; but they are adjusted with experience or practice.

So, what happens in this model is when there is a visual input visual input will leads to activity starting in the orthographic units which will leads to further activity in the hidden units. Hidden units is where the processing is actually happening and hidden units

is basically where the you know they will convert the visual input into phonological thing.

Every word is represented as a pattern of activation across the entire network how many phonological units are activated, how many orthographic units are activated, how many hidden units need to be employed here all of this every word will have an index which will basically give you the number of units activated across the unit. Learning to read basically in this kind of model will involve modifying the weights through experience.

So, how many words have to be basically read through the direct assembly direct route how many words will have to be read through the assembled phonology route; practice will basically tell this module practice will basically help this model associate those kind of weights. One processing unit is connected to others; so, that one processing unit is activated it will be able to influence the activation of other units as well.

So suppose there is some activation you are seeing orthographic unit because it is connected to hidden units and they are connected to phonological units there is already some activation there. Because it is connected to meanings semantics based units those activations will also go there and the entire network will get activated to start with once the event you start training this network on reading the connection weights will need to be randomized they just some random things and some inputs starts and the system starts reading.

But with practice as number of trials pass the system tries to zero in on the correct pronunciations.

(Refer Slide Time: 20:27)

- What's practice?
 - Training trials, upto 150,000. After activation has spread through the entire network, the pattern of activations at the output units (different pronunciations) are compared to the correct output. On basis of performance, weights are adjusted & performance improved.
- Advantage:
 - Simplest architecture that approximates human vwr performance.
- Evaluation:
 - *Phonological error score:*
 - Difference between model output & correct pronunciation.
 - Indicates whether the model pronounced correctly. & how quickly.

So, training you know up to 150 1015, 1000 20000 trials paining are there after activation has spread through the entire network the pattern of activation basically comes out as the output units and the whatever the pattern of activation is there in the output units is compared to what the correct output could be.

And this comparison keeps on going on and the idea is that eventually the network should learn to basically give output the correct pattern of activation in the output units as the correct output is there. So, the idea is the network gradually with practice with trials learns to let us figure out the correct pronunciation of each of these words. Now it seems like a little bit complex, but it is really not it is one of the very simple architecture of reading that kind of approximates human visual world recognition performance as well.

There are ways to look at this model that is one of the things called phonological errors score. And the phonological error score is basically just the difference of pronunciation between the correct pronunciation and whatever the pronunciation the model is giving you.

So, because you compare the correct output with the given output of the system you can kind of come up with a particular score. And the idea is with practice this phonological error score should be reducing and the correct output and the output that your system gives should kind of you know be congruent to each other should match each other.

(Refer Slide Time: 21:57)

- what happens after training?
 - After training error score was lower when compared to the correct output.
 - Model generated lower scores for words that it learned more. (like us.)
 - Model also produced regularization errors for low-frequency exception words (*brooch* was sounded as *book*)
 - Model produced longer response times for irregular words.
 - Model responded to non word stimuli like people, took long time to reject *brane*.

What happens after training? After training is happened after you have kind of train the model on 150000, 250000 trails what will happen then?

After training a particular errors score just I was saying phonological error etcetera would basically become lower as compared to the correct output. The idea is the in the machine is the system is trying to appropriate what the correct performance is the model will generate lower scores for words that it had learnt. Again I am talking about after training has happened the model also start using regularization errors for low frequency was just as humans would do.

So, if humans are basically reading words like brook as book you know the model will also start doing that you know because it is trying to match the actual performance. Also it was seen that this model produced longer response times for irregular words because it is difficult to read them using the assembled pronounce.

Model started responding to non word stimuli like people and it kind of started taking more time to reject words like brane as invalid word.

(Refer Slide Time: 23:09)

- What's practice?
 - Training trials, upto 150,000. After activation has spread through the entire network, the pattern of activations at the output units (different pronunciations) are compared to the correct output. On basis of performance, weights are adjusted & performance improved.
- Advantage:
 - Simplest architecture that approximates human vwr performance.
- Evaluation:
 - *Phonological error score:*
 - Difference between model output & correct pronunciation.
 - Indicates whether the model pronounced correctly. & how quickly.

So, after training has happened these are some of the effects that the model kind of shows before during training we already saw that you training this thing on 150, 250000 trials the model is trying to compare the output that it has come up with the correct output and is trying to figure out whatever the rules are needed, whatever changes are needed, whatever weight adjustments are needed to match the correct output in that learning happens and in that the model learns to read words you know.

(Refer Slide Time: 23:33)

- ## Dyslexia
- Single-route and dual-route models of word reading also compete to explain why some individuals have difficulty reading.
 - they compete to explain how and why some individuals suffer from *dyslexia*.
 - Dyslexia occurs when an individual has a problem reading, even though they are otherwise intellectually and behaviorally normal and have had the proper instruction and opportunity to practice reading.
 - Approximately 15% of males and 5% of females will suffer from developmental dyslexia (Stein & Walsh, 1997).

So, to speak; so, we talked about two models of three word reading we talked about the DRC model, dual route model and we talked about the DRC or the dual route model and we talked about the single route model. Now both of these models also tried to explain how difficulty in reading comes up.

So both of these models have tried to come up with explanations and explain how some people will suffer from a difficulty to read referred to as dyslexia. Now you must have all heard about dyslexia at various places its being one of the topics of discussion lately. So, dyslexia basically it occurs when a person has a problem in reading when somebody cannot really read properly.

Even though they are otherwise intellectually and behaviourally completely normal their IQ scores are good their visual analysis is good everything else is completely fine just that they are lacking this ability to read. So, its not really a major disorder you really. So, to speak it is not really debilitating disorder you might know of various people who done very well in the lives and have suffered from dyslexia earlier.

So, the idea is just about making this connection between the visual symbols and the sound symbol and finally, leading to meaning. So, approximately 15 percent of males and 5 percent of females anyways have suffered or will suffer from development dyslexia again this is data from 1997 from Stein and Walsh.

(Refer Slide Time: 24:59)

- There are some common threads that appear to cut across developmental and acquired dyslexia.
 - First, in both developmental and acquired dyslexia, there are people who have more trouble reading non-words, such as *feen*, than *exception words*— words that look like but sound different than other words, such as *have*.
 - Likewise, there are groups of both developmental and acquired dyslexics who have less trouble reading non-words than reading exception words.

And there are common threads there are common patterns of difficulties that developed dyslexia and acquired dyslexia have. Now I will just differentiate between developed dyslexia and acquired dyslexia developed dyslexia is something that already happens while the person is maturing you know during growing up here the child probably is not able to grasp the concepts of phonemic awareness. Or some you know reasons are there and because of it the child is not able to master reading that is developed dyslexia.

Acquired dyslexia is; suppose say for an example some injury has happened something has happened and that is lead to the difficulty in reading that could be referred to as acquired dyslexia. So, there have been different kinds of patterns that have been common across the kinds of dyslexia that are observed. One of the very important patterns is that there are people who have more trouble reading non words like if I write f e e n feen than exception words.

Suppose the words like have and say when those kind of things. So, there are people who have difficulty reading non words also there are groups of both developmental and acquired dyslexics who have been less trouble reading non words, but more you know than reading exception words. So, two kinds of people are there one who have more trouble reading non words, less trouble reading exception words and there are people who have more trouble reading exception words and less trouble reading non words.

So, this is sort of double dissociation that you will see for double dissociation it is basically you can refer to you know the earlier lectures that I have given in the last course.

(Refer Slide Time: 26:31)

- When an individual has greater trouble reading non-words than exception words, they are classified as *phonological* (or *deep*) *dyslexics* (Marshall & Newcome, 1973).
- When a person has less trouble reading non-words than reading exception words, they are classified as a *surface dyslexic*.
- It is important to recognize, however, that most dyslexics fall into the *mixed* category. That is, they perform below normal on a variety of reading and reading-related tasks. "Pure" cases of phonological and surface dyslexia are the exception rather than the rule, although "pure" cases have been observed.

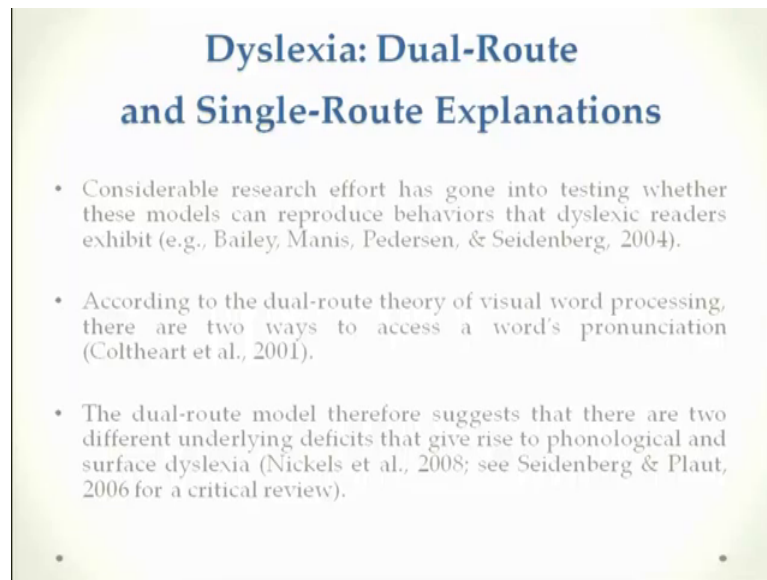

But double dissociation typically tells you that there are two different processes at work in these scales. So, when an individual has greater trouble reading non words and than exception words they are classifies as phonologic or deep dyslexics.

If they cannot read non words then they are probably having deep dyslexia or phonological dyslexia; the meaning is basically that they are not being able to use the phonological assembly route. When a person has trouble less trouble reading non words and they have more trouble reading exceptional words then they are referred to as surface dyslexics; the idea is that in surface dyslexics the meaning and the word connection is lost.

So, they can come up with a assembled phonology route they can come up with pronunciations etcetera or what has been lost with these people is the connection between the meaning and the sound part ok. So, the general problem is that they are not being able to connect meaning with the word form that they have activated.

It is very important to recognise; however, that most dyslexics will generally form into a mixed category, there will be some aspects of deep dyslexia some aspects of phonological dyslexia ok. So, they perform below normal on a variety of reading and reading related tasks and it is very rare that you will come across a pure phonological dyslexic or a pure surface dyslexic.

**Dyslexia: Dual-Route
and Single-Route Explanations**

- Considerable research effort has gone into testing whether these models can reproduce behaviors that dyslexic readers exhibit (e.g., Bailey, Manis, Pedersen, & Seidenberg, 2004).
- According to the dual-route theory of visual word processing, there are two ways to access a word's pronunciation (Coltheart et al., 2001).
- The dual-route model therefore suggests that there are two different underlying deficits that give rise to phonological and surface dyslexia (Nickels et al., 2008; see Seidenberg & Plaut, 2006 for a critical review).

So, both kind of models as I was saying basically have tried to explain how dyslexia happens. So, considerable research effort have really gone into testing whether these models can reproduce behaviour by dyslexic readers show.

Because if these models can really reproduce those behaviours you can try and mend these models and in the process try and help the people who have dyslexia as well; So, according to the dual route of theory of visual word processing there are two ways to you know come to a word pronunciation.

As I have already said assembled phonology route and the direct access route. So, the dual route model basically suggests that there are two different underlying this deficits that give rise to phonological dyslexia and surface dyslexia.

(Refer Slide Time: 28:39)

- Damage to the *assembled phonology* route leads to phonological dyslexia, as individuals lose the ability to “sound out” words that they have not seen before.
- Damage to the direct route leads to surface dyslexia, as individuals are compelled to “sound out” all words, even words like *have*, *pint*, and *yacht* that cannot be “sounded out.”

Let us look at that damaged to the assembled phonology route will lead to phonological dyslexia. Because the problem here is just coming up with the pronunciations because this assembled phonology route is damaged phonological dyslexia will happen, but these people can read exception words because the direct route is intact here ok.

So, these people will basically not be able to sound out words that are not accessible by their direct route that is one kind of dyslexia. And on the other hand if there is damage to the direct route this would lead to the surface dyslexia because the link between the word form and the meaning is lost. These people will be compelled to sound out all the words they will use the assembled phonology route more often and they will lead to regularization errors like reading p i n t as pint and not as pint.

(Refer Slide Time: 29:35)

- Single-route models of reading view word reading as resulting from the operation of a unified neural network, with different kinds of impairment resulting from different types of damage within the system (Harm & Seidenberg, 2004; Woollams et al., 2007).
- Phonological dyslexia can be modeled within this framework as resulting from damage to units that represent the phonological (sound) codes needed to pronounce words.
- Surface dyslexia can result from changes to other aspects of the model, such as the number of processing units available to the system (which can be thought of as the amount of processing resources that the system can dedicate to the task), or the rate at which the system can learn from feedback.

So, these are the two deficits which are leading to two kinds of dyslexia according to the dual route model of reading. Single route models of reading view word reading as resulting from the operation of a unified neural network.

So, if you remember the parallel model which I was talking about the single route model has everything linked to each other. So, it is you know it is not possible that just one of them is lost or something like that just the DRC was saying ok. So, with under this kind of explanatory mechanism different kinds of impairment result from different types of damage within the same system ok.

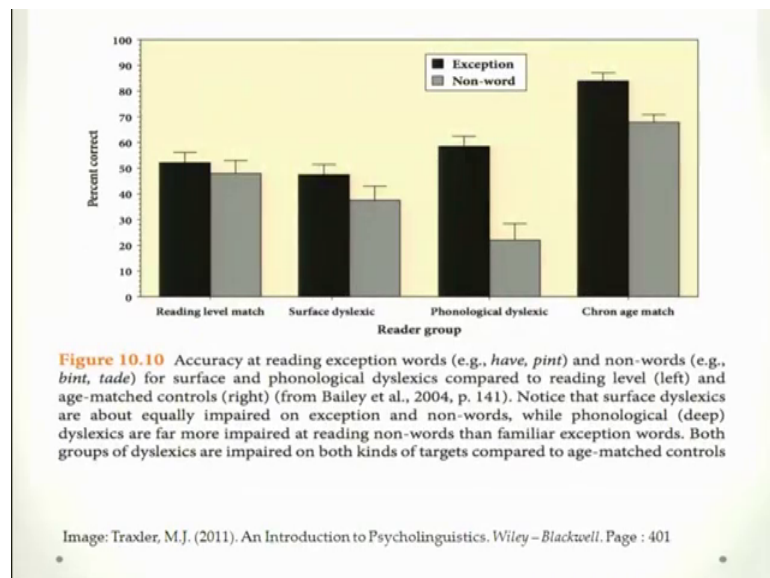

So, phonological dyslexia here can be model within the framework as a result of damage to the unit that are representing the phonological codes. So, the phonological units will be damaged surface dyslexia can result from changes to other aspects of the model suppose some of the hidden units are damaged or the connection between the hidden units and the meaning units are lost. So, again it is the same system different aspects of system might be damaged to lead to different kind of patterns of dyslexia.

(Refer Slide Time: 30:33)

- So, while single-route models view non-word and exception-word reading as being governed by the same sets of representational units running the same processes, different kinds of dyslexia reflect different underlying deficits, as different kinds of damage to the system produce different patterns of behavior.

So, while single route models view non word and exception word reading as being governed by the same sets of representational units, running the same processes different kinds of dyslexia might reflect different underlying deficits as different kinds of damage to the system will lead to different patterns of behaviour. I am not saying there are two different systems I am saying they different patterns of dyslexia are arising because different aspects of this same unified systems are damaged.

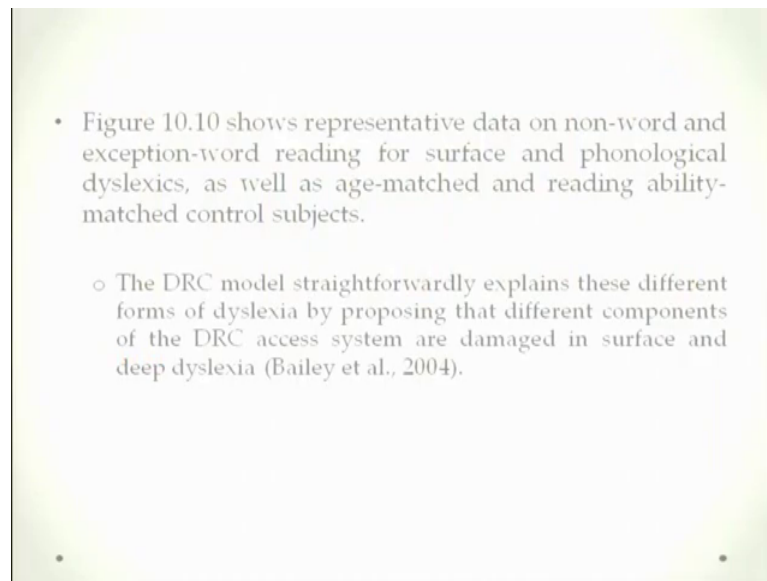

(Refer Slide Time: 31:01)

Here I will just show you just the reading performance of reading at exception words for both surface dyslexics and phonological dyslexics. You can see that there is the second left and there is a phonological dyslexic dyslexic and then at the end extreme right there is a chronological age match.

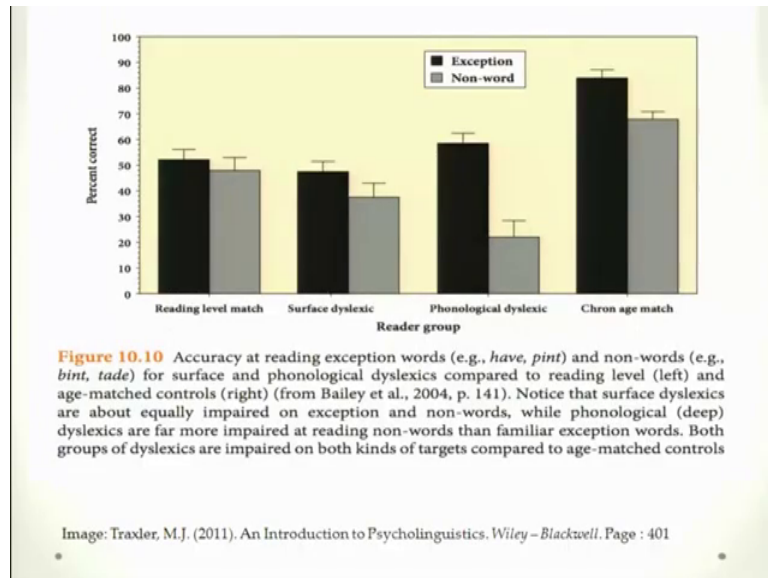

So, we will just try to see how this reading performance can be explained by the two models.

(Refer Slide Time: 31:25)

Now, this figure basically as I was just mentioning shows representative data on non word reading and exception word reading for both surface dyslexics and phonologic dyslexics.

(Refer Slide Time: 31:38)

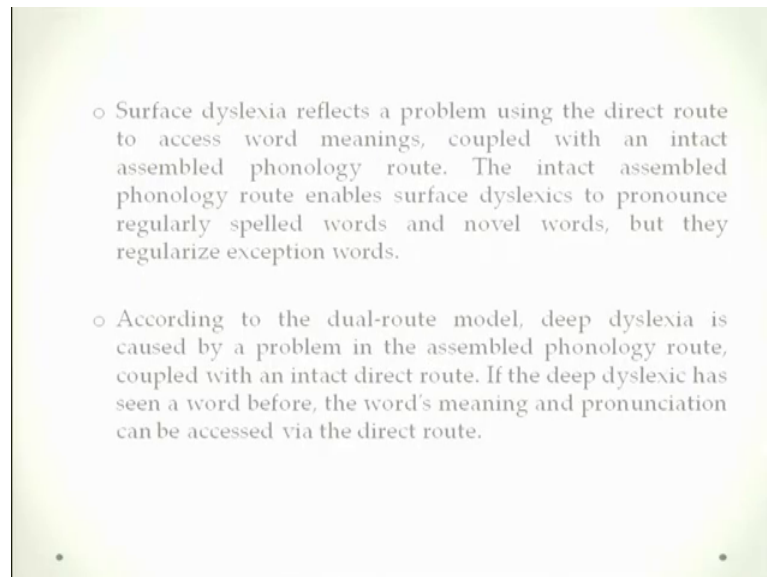

You can see here that surface dyslexics are more correct at reading exception words phonological dyslexics are also slightly more correct in reading exception words, but there is a great mismatch between exception word and non word reading in phonological dyslexics and surface and exception word and non word reading between surface dyslexics.

(Refer Slide Time: 31:59)

- Figure 10.10 shows representative data on non-word and exception-word reading for surface and phonological dyslexics, as well as age-matched and reading ability-matched control subjects.
 - The DRC model straightforwardly explains these different forms of dyslexia by proposing that different components of the DRC access system are damaged in surface and deep dyslexia (Bailey et al., 2004).

So, DRC model can explain these findings very straight forwardly by proposing that different concepts of the DRC different routes of the DRC system are damaged in surface and phonological dyslexia.

(Refer Slide Time: 32:12)

Surface dyslexia basically reflex again I am just kind of revising whatever I have said surface dyslexia represents problem using the direct route to access word meanings compiled with an intact phonological route. So, phonological route is fine just the link between word meaning and word form is lost.

The intact assembled phonology route will enable the surface dyslexics to pronounce regularly spelled words and novel words, but they will not be able to pronounce correctly the exception words. According to dual route model deep dyslexia is caused by a problem in the assembled phonology route which is coupled with an indirect with an intact direct access route.

So, here the direct access route is fine the assembled phonology route is a problem. So, exception words these people will be able to read better, but phonological words I mean the regular words will probably have a problem in reading.

(Refer Slide Time: 33:07)

- If the deep dyslexic has *not* seen the word before, the assembled phonology route is not able to compile a pronunciation, and the resulting pronunciation is usually unrelated to the correct pronunciation.
- When the DRC model is used to simulate dyslexic symptoms, separate lesions in the direct route and the assembled phonology route are necessary to capture the kinds of behavior exhibited by patients with different types of dyslexia (Nickels et al., 2008).

If the deep dyslexic that is the phonologic dyslexic has not seen a word before the assembled phonology route will not be able to compile a pronunciation and the resulting pronunciation will sometimes become unrelated to the actual pronunciation because that assembled phonology route is not working.

While the DRC model has been used to simulate the dyslexic symptoms separate lesions have you know separate damages have in the direct route and the assembled phonology route are necessary to mimic the behaviour of surface dyslexic or phonologic and deep dyslexic.

(Refer Slide Time: 33:44)

- Single-route models have also been used to capture aspects of dyslexia.
 - For example, the original Seidenberg and McClelland model could simulate some aspects of poor word reading.
 - When half of the hidden units in the model were removed, its error scores for high-frequency words were at about the same level as the error scores for low-frequency words in the full model.
 - This reduction in the number of hidden units had a greater effect for irregular than for regular words, which suggests that a greater number of hidden units is necessary for the model to represent the item-specific information that is required to pronounce exception words accurately.

In single route models people have also tried to capture how dyslexic perform and what has been found is for example, in the original Seidenberg and McClelland model.

It could simulate some aspects of poor word reading and it basically was when half of the hidden units in the models were removed the error scores were high frequency words are about the same level as error scores for error score for low frequency words. So, the idea is the number of units are damaged and that is leading to problems in reading.

This reduction in the number of hidden units had a greater effect for irregular rather than regular words which suggests that a greater number of hidden units is necessary for the model to represent item specific information you know more resources are needed for item specific reading to happen.

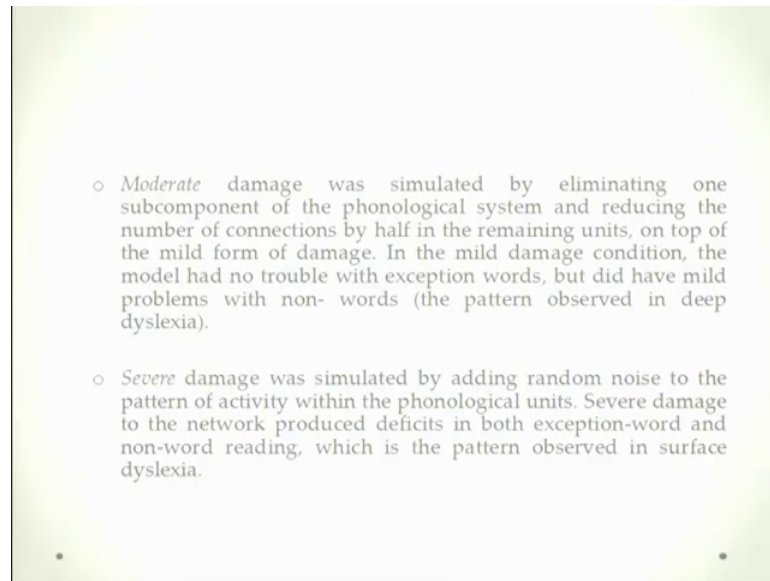

(Refer Slide Time: 34:29)

- A subsequent model adopted a more complex system of phonological representations and was trained on phonology before it was trained to recognize words from print (Harm & Seidenberg, 1999).
 - When the phonological representations in this model were degraded in different ways, different patterns of reading performance emerged.
 - *Mild* damage to the network was imposed by limiting the degree to which representations of different phonemes differed from one another.

Also a subsequent model, a different model has been adopted to you know explain more complex system of phonological representations. And then it was trained on phonology before it you know it was kind of trained to read using for phonology to recognize words.

And when these phonological representations in this model were degraded in different ways then different patterns of reading difficulty emerge. So, if these phonological units suffered mild damage then the basically the network you know was limited by it could not read the representations from different phonemes differed from each others; different kinds of sounds being represented by same letters.

(Refer Slide Time: 35:07)

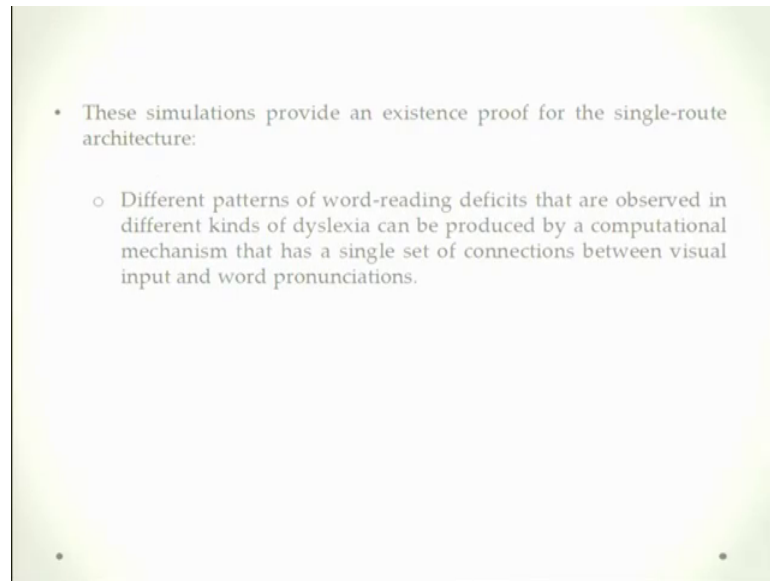

When the damage was moderate from mild to little bit more moderate this was directly simulated by eliminating just one component of the phonological system and reducing the number of connections in half in the remaining units on top of the mild damage; this kind of damage you know in this mild damage condition model had no trouble reading exception words, but it could not read the phonological words.

It had major it had mild problem with the reading from the phonological route. When a severe damage was there and most of these phonological units were damaged then basically what happened was that a severe damage to this network was produced deficits in both exceptional word reading and reading normal words using the assembled phonological route.

So, this is one of the ways in which people have tried to mimic reading of words using these single route computational models.

(Refer Slide Time: 36:00)

These simulations basically have kind of you know pointed towards the possible proof for existence of single route architecture. So, the idea is that these models try and point out and say that it is just that you know it could be a unified system the extent of damage to that unified system will lead to different extents of patterns of surface dyslexia and you know dyslexia appearing.

So, again this is something which is going on I do not think really think that this debate is settled, but the idea is that different patterns of word reading deficits that are observed in different kinds of dyslexia might be produced by computational mechanism that has a single set of connections between the visual input. So, I think this is all from me about reading and dyslexia and word reading I will talk to you about something else in the different lecture.

Thank you.
