Properties of Poisson Process (Part 1)

So okay, let us continue our discussion on a Poisson process. So, before that, in the last class, we introduce what is a stochastic process and then we introduce some properties like what is a counting process and there what we meant by independent increments. And based on these properties, we defined a process called Poisson process. So, if you are going to look at some of the properties of this Poisson process and try to prove them as we will see that these properties you can directly derive from the definition and they are also very appealing in the sense when you want to do kind of a counting this property is what you desire.

(Refer Slide Time: (01:20))

So, these are the properties we said let then is if a Poisson process, a random processes is a Poisson process with rate λ that means N is a counting process and has independent increments and if you take any interval or any indices T and S then the number of counts. So we said that this is $N_t - N_s$ has Poisson distribution with the rate which is λ times the length of that interval minus t minus s . So, we are going to today see the following properties.

(Refer Slide time: 02:10)

Process (P_p)

process is P_p with rate λ .

counting process

dependent increments

has the $\text{po}(N(t,s))$

in $V \leq s$ and x

Proposition: Let N is a counting process and $\lambda > 0$. Then following are equivalent.

- N is a P_p with rate λ
- The inter count times $U_1, U_2, \dots$ are mutually independent $\text{Exp}(\lambda)$ random Variable $N_1 \sim \text{Poi}(\lambda t)$
- For each $t \geq 0$, N_t is $\text{Poi}(\lambda t)$ and for any $n \geq 1$, the conditional density of the first n count times $(T_1, \dots, T_n)$ given $\{N_t = n\}$ is

$$f(t_1, \dots, t_n) = \begin{cases} \frac{n!}{t^n} & 0 < t_1 < t_2 < \dots < t_n \\ 0 & \text{o.w.} \end{cases}$$

Proposition: Let N is a counting process and $\lambda > 0$. Then following are equivalent.

- N is a P_p with rate λ
- The inter count times $U_1, U_2, \dots$ are mutually independent $\text{Exp}(\lambda)$ random Variable $N_1 \sim \text{Poi}(\lambda t)$
- For each $t \geq 0$, N_t is $\text{Poi}(\lambda t)$ and for any $n \geq 1$, the conditional density of the first n count times $(T_1, \dots, T_n)$ given $\{N_t = n\}$ is

$$f(t_1, \dots, t_n) = \begin{cases} \frac{n!}{t^n} & 0 < t_1 < t_2 < \dots < t_n \\ 0 & \text{o.w.} \end{cases}$$

So, we had said some random process to be a Poisson process, now we are saying that it has other equivalent characterization, that is you can say up N is a Poisson process with λ that is equivalent to saying that inter count times U_1, U_2 , so remember we have already defined what we mean by inter count times that is between two count the time elapsed. So, that I am going to denote as this random variable U_1, U_2 .

Okay, so they are random variables, right for a process, the time between two successive counts can be random so that is why I am denoting them as U_1, U_2 they are these inter count times they are mutually independent and also exponentially distributed with parameter λ . So, all these

U_1, U_2 they are identically distributed further independent and common distribution is exponential distribution.

And this is same as saying if you are going to take any τ positive then N_τ , what is this N_τ ? This is in the process the random variable index that time τ is Poisson with rate $\lambda \tau$. So if you are going to take any τ , this N_τ is Poisson distributed with $\lambda \tau$ and if we are going to take any N the conditional density of the first n count times, remember earlier we have defined small t_1, t_2, t_3 like t_1 was the first count time, t_2 was the second count time like that.

But this count itself can happen at random times. So that is why I am now going to denote them as random variables with capital letters. And if we are going to look at the first N count times, and that joint distribution that joint distribution is given conditioned on the fact that this N_τ has taken the value N that is going to be given us $N!$ divided by τ^n .

So, we are saying this is A same as saying B, B is same as saying C or A same as saying C all these are one implies the other okay. So, okay just now from this property, we are going to look them try to prove each one of them today what is saying is if I have a Poisson process, okay then that time of arrival between any two counts or the interval between any two counts is going to be exponentially distributed with rate λ .

And these intervals are going to be independent. The distribution of these (independent) intervals is going to be independent and further now if you look, focus on this. Okay, so I missed it, this is conditioned on the $E[N_\tau]$ suppose let us say N_τ if the Poisson processes that at the time τ N count is happened you are conditioned upon in this. Now you want to see that what is the joint distribution of this?

So, first count happened at time index T_1 , second count happened at T_2 and let us say N th count happened at time T_n , these distribution is going to be expressed like this. Okay and I should also so notice that I am already saying till time small τ , N counts is happened. And the joint distribution of these times is going to be this. So now if you focus on this part, forget numerator. Now it is going to be like just now $1/\tau^n$ to the power n right.

So if I am going to look at the distribution of n random variables and if it happens that their joint distribution is $1/\tau^n$, can you say something about what this joint

distribution looks like? So just take N equals to 1, so I am saying 1 upon τ . So in the interval, τ , I am saying something like the PDF is constant 1 upon τ what that corresponds to? Any form, right something now I am saying that joint distribution of N random variable is kind of 1 upon τ to the power N , it what does this imply in a way, what? Yeah there are N uniformly distributed random variable each with parameter τ and they are independent right.

So, they are getting multiplied, 1 upon τ into 1 upon τ into further I have to look it such kind of ordering these uniform random variables. Further, I need to condition that the outcome of the first random variable is smaller than the outcome of the second variable. And outcome of the second random variable is smaller than the outcome of the third random variable. So, I need to further condition on this.

So, if I further condition on this, I am going to get this factor 1 by N factorial in the denominator. So, when it the N Factor goes in the numerator. So, this these N factor is coming due to the fact that I am looking for this t_1, t_2 be such that they are arranged in the increasing order. So in that way there are two distributions that are related to my Poisson distribution, one is what? The exponential distribution that is the inter arrival, the inter count times are exponentially distributed.

And now, if you look at the directly the time of the count itself and the joint distribution, there seems to be some kind of uniform distribution that is coming into a picture here. So let us try to prove. Now what we are going to do to complete this proposition theorem, we need to show that each one of them implies each right.

So, I have to show that A implies B , A also implies C and if I take B , it should be okay that B implies A as well as B implies C as well as if I take C it should be the case that C implies A and C implies B . So, instead of trying all this thought will try to show is A implies B and we ensure that B implies C . So, ensure that A implies B and then B implies C , so, that should be sufficient right to show that each one C implies B is already, C okay Oh sorry I had to do this and I did not do this, okay let us say.

(Refer Slide Time: 11:03)

Let us try to show that A implies C. So let us assume that N is a Poisson process. So as soon as I assume N is a Poisson process, I have all these properties available to me, because that is the meaning of N is a Poisson process. So now, let us take any N real numbers such that they are ordered like this T_1, T_2 all the way up to T_n where T_2 is going to be larger than T_1 and so on like this. So now think of them as. So this is T_1 , this is T_2 all the way up to let us say T_n . So let us take an epsilon.

And now what I am going to do is I am going to look at a small region. So I will just take an epsilon and just go behind T_1 and get T_1 minus epsilon and similarly around this, I will go slightly epsilon behind and get it to minus epsilon and this is like T_n minus epsilon, okay now what I want to do is I want to look at this intervals here. So this means I am open at this point, closed at this point and similarly okay, now let us try to find joint distribution of.

So what is this T_1, T_2 ? These are the count times and these are the random variable, so let us try to understand. Now let us try to find what is the probability that so what is T_1 here, capital T_1 ? The time when the first count happens, right? So let us assume I am interested in this T_i belongs to, okay, so what is this telling? I am interested in when I take T_1 . I am asking the question, the probability that the first count happen in this interval T_1 .

So T_1, T_2 they are given some numbers to me. Now, T_i is a random variable right, now I am basically asking the question, okay this T_i that means i th count happening in this interval, okay

and now I want I am looking at a joint distribution and I want this to happen, this condition for all $i = 1$ to N .

Now if I now I want to express this in such a way that I can go and apply my independent increment properties. So I want let us say I want to apply this, how can I express this probability to exploit my independent increment property? So one thing I can now do is what I am basically asking is the first count should be happening here, right? That is T_1 , capital T_1 is T_1 minus epsilon and T_1 . If that is the case, then there should be no count happened before that, right?

And the first count should have happened here. And then if I want T_2 to be again in this interval, they should know count I should have happened in this interval and the next count should have happened in this interval. Then then my T_2 is going to fall in this interval right. So then this is same as asking, is this correct? I can express this joint distributions like this.

That is nothing happens here and the first count happened here and second count only happened here. That means nothing I do not want any count to happen here and like that and the last count happens only in this region. So, you see that now I have expressed this quantity in terms like in terms of the increments. Okay, so now I want to expand this. If N is a Poisson process are this all of these events are independent or not? Because I am looking at a different-different intervals, right. And I know that for Poisson process, they are all independent.

(Refer Slide Time: 18:33)

The slide shows a lecturer in a light purple shirt standing next to a green chalkboard. The chalkboard contains the following handwritten text:

IE 611

Poisson Process (P_p)

$$= P\left\{\sum_{i=1}^n N_{t_i} - N_{t_{i-1}} = 1\right\}$$

$$= P\left\{N_{t_1} - N_0 = 0\right\} P\left\{N_{t_2} - N_{t_1} = 1\right\}$$

$$= \frac{e^{-\lambda t_1} \lambda^0}{0!} \cdot \frac{e^{-\lambda t_2} \lambda^1}{1!} \cdot \frac{e^{-\lambda t_3} \lambda^0}{0!} \cdot \frac{e^{-\lambda t_4} \lambda^1}{1!} \cdot \dots \cdot \frac{e^{-\lambda t_n} \lambda^0}{0!} \cdot \frac{e^{-\lambda t_n} \lambda^1}{1!}$$

$$= \lambda^n e^{-\lambda t_n}$$

On the right side of the slide, there is a definition of the probability mass function:

$$f_X(x) = \lim_{\epsilon \rightarrow 0} \frac{P\{X \in [x, x+\epsilon]\}}{\epsilon}$$

Below this, it says "Proposition" and "and".

Below that, it says "N is" and "The in" and "mutu" and "Varia" and "For" and "for any" and "the" and "give" and "f".

At the bottom right, there is a small logo for NPTEL.

So, and now I am going to further exploit the property that, so now if I am going to look at. now first consider the case. So I can write them as probably okay, just let me write it for in terms of the probability first, probability this is for the first one and the last one is going to be right I simply applied my probabilities on each one of this, yes right.

Now, this is coming from what like as I said, this is coming from independent increment properties. Now further what is the third property of the Poisson process? It is going to be Poisson, right? Like if you are going to so I could as well, write this guy as like n minus 0 here at 1. And I could just take n 0 as 0 itself.

Now what is this probability is going to be? Sorry, this is 0. What is this? What is the length of this interval? $T_1 - \epsilon$ and I am asking, so this is going to be Poisson process with what rate? $\lambda(T_1 - \epsilon)$ right. Now, what is the probability that a Poisson process with rate $\lambda(T_1 - \epsilon)$ takes a value zero? $e^{-\lambda(T_1 - \epsilon)}$ here the length of interval is simply $T_1 - \epsilon$ right?

Now, what is the probability that it takes value 1? The length of the interval here is it is simply ϵ . So here it is a Poisson process with rate $\lambda\epsilon$ right. And what is this value is going to be? $\lambda\epsilon$ into $\lambda\epsilon$ and there is a one factor in the denominator which we can escape, right. So, like this, you can keep writing for all of them. And just let us write what is this looks like $e^{-\lambda\epsilon}$, this is going to be what? $T_n - 1 - \epsilon$ and the final one is going to look like $\lambda(T_n - \epsilon)$ here this is going to look like $\epsilon e^{-\lambda\epsilon}$ okay.

So if now I am going to simplify all these things that are how many $\lambda\epsilon$ multiply getting multiplied here? There are going to be N one of them and if you go into simplify all of them, you see that some subtraction is going to happen because T_1 is happening it will also come as minus T_1 later. And if you going to simplify that, what it will end up is simply $e^{-\lambda T_n}$ okay, so whatever this probability I was looking at this joint distribution it is now $\lambda\epsilon$.

So this I am going to simply write as $\lambda^n \epsilon^n$ into λT_n and now let us say I am now want to take this probability that T_i belongs $T_i - \epsilon$ divided by power ϵ^n this is going to be equals to λ^n , A power $e^{-\lambda T_n}$, right that is what I have shown. So now if you are now going to, see what I am doing here for a given T_1, T_2, T_n I am looking at for each of these T_i around an interval of ϵ length.

And now everywhere these lengths are of ϵ . So what I am basically looking at for a given this T_1, T_2 I am looking at the mass of this random variables in a ball, which is of what volume? So for example, let us take a simple case I have now taken, let us say this is my T_1 and this is my T_2 and T_1 I have looked at interval of ϵ and also on T_2 I have also looked at and volume of ϵ .

So what is this region is going to be? This region is going to be I was basically looking for my T_1 , T_2 to be in this region here, right? Where T_1 is of length ϵ and T_2 is also of length ϵ . So what is the area here? ϵ^2 , right. So if you are going to extend it to N dimension, what is this volume is going to be? ϵ^N , so now this is what I want to do. I was basically looking at this joint distributions to lie in some volume which has, which is ϵ^N .

Now, that probability I am dividing it by ϵ^N . And now I have what is what is λ^N , e^{λ^N} . Now, this ϵ I have chosen is arbitrary right? I could as well, let this ϵ go to infinity here, even if I take ϵ arbitrary small, this ratio is kind of independent of λ and right this value is going to remain the same. So if I take this ratio and let ϵ going let ϵ tend to 0, what this ratio will convert what is this ratio according to our definition?

So, you remember the way how we defined our CDF, sorry PDF and we corrected it to the probability? So, what we had said? We had said that f of x at a point x can be thought as limit as this is in all one dimensional case as ϵ tends to 0, probability that x is let us say, in this interval $x - \epsilon$ to $x + \epsilon$ divided by ϵ , did we say this? Then we are try to argue the relation between a problem when we try to do interpretation of what we mean by media PDF of a point, at a given point.

So we are dealing here with what like we are dealing here with continuous random variables right, this T is here, are the continuous random variables? T is the count time right, they can take any number on the real value. So, here we are dealing with continuous random variables. So, when we try to give interpretation for our PDF, we had said that, PDF of a random variable x at a point x can be thought of its probability in the neighborhood of x , where that neighborhood is defined in terms of ϵ .

And we can make that neighborhood small by letting ϵ go to 0 and when we take this ratio that is nothing but a PDF, yeah.

Student: () (29:02)

Professor: Ti, yeah these are finite, but each one of them can be a continuous random variable. I am talking about individual one right. So each one of them itself is a it can take any (position) any real number. So, if you have this probability and if you just like epsilon go to 0 in this fashion that is nothing but the CDF. Now, we can apply the same definition here, right. But here is sort of a real line we are in a N dimensional space. That is what instead of just epsilon we are looking at epsilon to the power n which corresponds to area which is the volume in the N dimensional space.

(Refer Slide Time: 29:57)

So, due to this we could now write a f of, f of T_1, T_2 all the way up to T_n the joint distribution of this should be what, $\lambda^n e^{-\lambda t_n}$ provided what is this, this T_1 is greater than T_2 and all the way up to T_n and now we have 0 otherwise. This is correct? Are you convinced? And what is this? This is the joint distribution of these random variables. So, this is what we just derived by using the properties of my Poisson process.

So, it is clear that we use our second property here of the Poisson process that independent increments and then we use the properties of poisson distribution, the third property here. So, did we use anywhere the property, the first property which said that the poisson process is a counting process? Whenever use it right because one of the, what is one of the properties of the counting process? N of 0 is 0, right?

I mean, we use part of that counting processes much more, but we partly used some part of the definition it being a counting process here. Okay, now we have but this is not what we are interested in right? Fine, we have come up with the joint distribution of my count times. But what I am interested to show property B is, the distribution of my inter count times. Okay now how to drive a joint distribution of the inter count times using the join distribution of this count times themselves?

So, if you want to drive what property you can exploit now? Is there a way you can think of? So, from this I basically want to know go and write what is the distribution, the join distribution of this random variables? So, if there is a relation between this U_i s and this T_i s I should be able to apply my transformation of random variables properties and should be able to drive this right. We already studied that, but for now the question is what is the relation between this U s and T s?

So we already know that right like $U_i = T_i - T_{i-1}$. So, we know this relation, now how can we write this joint distribution in terms of f of x , f of T s here? What is the property, what is that we know about this? So, we know that right when we have to write this distribution, we need to compute the Jacobean. So, what is the thing? So, we have this so, let me write it more explicit, we have U_1 equals to T_1 , U_2 equals to $T_2 - T_1$ and like that and also we know the other way around right.

So, T_1 anyway equals to U_1 and what is T_2 ? U_1 plus U_2 and T_3 is $U_3 + U_2 + U_1$, all this we know right. So, how to write this then? So we already know that this is nothing but U_1 to U_n of U_1, U_2 to U_n is equals to f of T_1, T_1, T_1 way up to T_n what was this and what we have here? A Jacobean matrix, right, determinant of a Jacobean matrix and what was that? So, can somebody quickly compute what is the Jacobean matrix here? Is it going to be 1? Why is that?

You are just going to get a, so what I written just compute that and finally, whatever we want here we will have a unit determinant. So now how to express this? I have this T_1 but T_1 is U_1 and T_n is sum of all the random variable, but this distribution only depends or it should be T_n here and T_n here So, what is T_n in terms of U s? T_n is nothing but some of U is right.

So, because of that you could write it as $\lambda^n \cdot U$ to the power minus λ and this is for any U and this is going to be 0 otherwise. Now from this, did we conclude what we wanted to say here? I am looking at the joint distribution of U_1, U_2 all the way up to U_n , now what I have

done is finally able to show that give me any U this can be express as λ to be power N , E to be power λU_1 plus U_2 up to U_n .

So, what is this basically? This is nothing but the product like λE to the power, λE to the power λU_1 into λ times E to the power minus λU_2 like that right I can split it as a product of N such terms and what is each terms there, what is each term there? Is a exponential random variable with parameter λ . So, that is what exactly the claim and why I am saying independent? Because this joint distribution I am able to express is a product of N distributions, right. And each one of them now corresponding to exponential random variable with λ , so that is how this claim holds.

Okay, so as you see, I mean, if you highlight Gosh, if I have Poisson process that means nothing but if you just look into the entire count times, the collection of inter count times they are nothing but they are Poisson distribution with the same rate λ . So, if I say, I Poisson process with rate λ , or I say I have a bunch of random variables, which poise a random process where each random variables are independent and everybody has a Poisson distributed with rate λ . That means I am basically referring to the same poison process with rate λ .
