Introduction to System Dynamics Modeling Prof. Jayendran Venkateswaran Department of Industrial Engineering and Operations Research Indian Institute of Technology, Bombay

Lecture – 16.4 Modeling Oscillations Part – II

Hello, today's lecture we are going to look at Modeling Oscillations in couple of different systems. So, in this lecture we are going to build a system dynamics model of a business decision making potentially resulting in oscillatory behaviour. We are making this model we will try to understand what causes oscillations oscillatory behaviour in system dynamic models. Let us consider the production inventory scenario.

(Refer Slide Time: 00:51)

A Production-Inventory Scenario

- Consider a labor intensive industry as follows.
- A village cottage industry makes handicrafts (viz. dolls). The company's production completely depends on the number of people employed. Each employee makes 50 dolls a month, and are contracted to do so.
- Since the sales is about 1000 lamps per month, the company would like maintain 1000 lamps in inventory. The company adjusts any discrepancy in the inventory level within 2 months, on the average. Based on the required production (to fill the inventory gap), the company estimates the required people, and hire (or fire)
- Semployees. The average <u>hiring</u> (or firing) delay is 0.5 months.

Model and simulate this as SFD over a 2 year period.

Let us consider a labor intensive industry as follows, a village cottage industry makes handicrafts say dolls. The company's production completely depends on the number of people employed. Each employee makes 50 dolls a month and are contracted to do so.

Since the sale is about 1000 lamps per month, the company would like to maintain 1000 lamps in inventory. The company adjusts any discrepancy inventory level within 2 months on an average. Based on the required production to fill the inventory gap, the company estimates the required people and hire or fire employees. The average hiring or firing delays half a month. We would like to model and simulate this stock flow diagram over a 2 year period.

Now, whenever we are presented such scenarios we would like to see what is the stock and flows within this system. Now, let us go back and read the description to see whether we can identify some stocks and flows. One of the obvious thing is we get an example of a physical inventory system is when you freeze system, we end up seeing lot of inventory right. So, inventory becomes a natural stock within the system. So, inventory will be a stock.

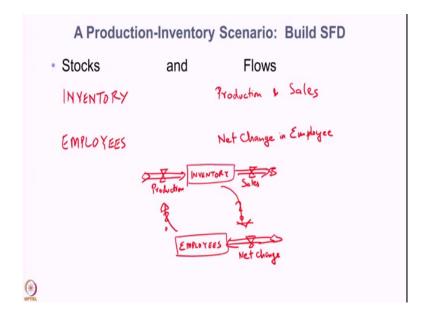

Now, if inventory is a stock then something should be the flow into and out of the inventory. So, whenever a sales happen; inventory is going to reduce right that is pretty intuitive. So, sales becomes a flow; out of the which reduces inventory levels and what adds to the inventory; production company's production must add to the inventory. So, production is another flow that affects your stock of inventory.

Now, what could be the other stock; in a company or a factory whenever you can you know imagine ah snapshot of a factory the only couple of things that we are going to see. Imagine a photo that has taken of factory; you are going to see machines, you are going to see inventory of goods and you are going to also see the employees or the people.

So, the next talk could be the employees or the people in the company; let us see based on the people or employees over here. Let us just circle the employees this could be the another stock and it clearly says that these employees can be hired or fired on a short term basis.

So, this hiring or firing is just the act of hiring or firing itself becomes a flow which is governed by hiring and firing delay which is slightly different. So, now we identified the basic stocks and flows for this scenario. So let us go ahead and develop a stock flow model.

(Refer Slide Time: 03:54)

Let look at this stocks and flows we have just written it. So, let us just write it out the stocks are inventory and employees on the flows; that is flow in to the inventory is going to be production and flow out of inventory is going to be sales. And employees are going to be affected by the hiring or let us just call it as net change in employees; what you mean by net change in employee numbers.

So, this system pretty much captures the following. So, we have inventory, sales, production and here we have employees. Let us just call it as net change in employees, just rewriting the stocks and flows in terms of the diagram that were used to.

Now, two things are going to happen; if you are in this model employees somehow is affecting the production and the sales or rather the inventory is somehow going to affect how many employees I need within the system. So, this stock is going to affect the rate at which the inventory stock is going to change. The inventory stock is going to affect the rate at which the employee stock is going to change.

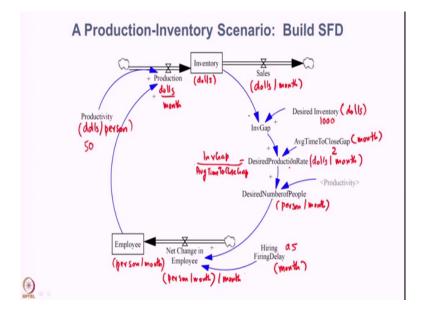

Now, let us see how that can be achieved; if you go back to the description; it says that production depends on the completely depends on number of employee people employed, production completely depends on the employ number of people employed and each employee makes 50 dolls a month. So, if I know the number of employees and we already know their productivity; so the production can be easily computed by the number of employees times their productivity.

Now, the company the next bullet point it says that the company would like to maintain 100 lamps in inventory; that means, that is your desired inventory level in the company. And if there is a gap between this desired level as well as the actual inventory level, it says the company would like to adjust is discrepancy within 2 months. Adjust the discrepancy means that if I have too much inventory then I have to reduce my inventory level; if I have very less inventory, I have to increase my inventory level.

How to increase or decrease inventory level? Sales is external to the company; sales is about 100 lamps and is external to the company. The only way we can adjust in inventory level is by changing the production, now what changes the production? Production can only be changed by the number of employees because if you hire an employee; he is he or she is going to make 50 dolls a month. So, only way is if I hire more people, if I want to increase my inventory level or I have to keep less people so that I can produce less hence my inventory level will fall down.

So, if based on the discrepancy inventory; we can compute what is the required production rate that is needed and based on that, we can estimate the number of required number of people and which will then result in hiring or firing which will affect the net change in the employees, which will affect the employee stock.

(Refer Slide Time: 08:27)

Now, if we model what I just told in a stock flow diagram; this is what you will see. So, we have already seen the inventory production and sales, as well as employee and net change in employees as the stocks and flows. Let us see what is connecting them before that let us go ahead and write some of the units.

So, the units of inventory let us keep it as dolls so; that means, sales is going to be dolls per month, production is also going to be dolls per month. Now, desired inventory again is going to be dolls; inventory gap is nothing, but desired inventory minus the actual inventory average time to close the gap; again it will be in months. We already know the values the desired inventory value is 1000; average time to close the gap is given as 2 months.

Now, I have inventory gap and it; it can take 2 months to close that gap. So, desired production can be defined as inventory gap divided by the average time to close the gap. So, that is nothing, but my dolls per month. So, desired production rate is equal to the equations underlying; it will be inventory gap over average time to close the gap.

Now, let us go back to the left side; now we have something called as productivity. Productivity is nothing, but the number of dolls produced per person or per employee and the values has been given as 50 dolls per person.

Now, number of employees the units can also be set as a person; thus the production is nothing, but productivity into employees ok. Now yeah, but if you do that you can see that the units of production is actually nothing, but just dolls right. Dolls productivity production is defined as productivity multiplied by the number of employees, then the units is not going to match.

Now, in that sense let us actually observe what is happening with the employees. The number of employees though it seems like a just counting a person, it actually varies monthly right. So, this stock the units of this stock actually has to be person per month. Thus the units of net change in employees will naturally become person per month over month.

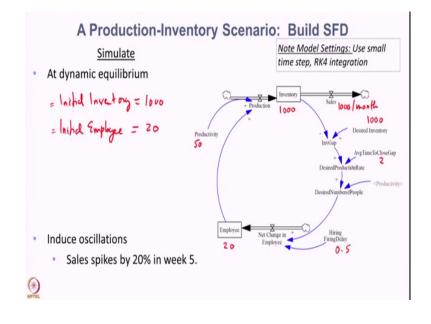

So, this employee stock now represents a number of people in that particular month; hiring and firing delays of course, the month is the units and it has been given as value has been given as 0.5. Net change in employee is nothing, but the desired number of people divided by hiring and firing delay.

Now, how do we get the desired number of people? I know how much the production rate we want, we already know that desired production rate. And that if we get divided by the

productivity we are going to get the desired number of people which will be nothing, but the units of it will be person per month correct.

So, desired production rate is dolls per month, it is converted into person per month through this productivity variable. Since we know each person is going to make 50, desired number of people can be easily estimated based on the desired production rate. So, let us go ahead and try to simulate it.

(Refer Slide Time: 13:03)

Now, first again note the model settings here we will be using a small time step with RK4 integration to get a good precision. Now, when we simulate; we would like to start the model at dynamic equilibrium.

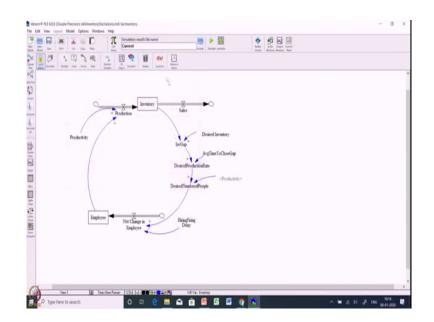

So, to do that let us see; remember the only values that we know are or which has been explicitly given are desired inventory is 1000, time to close gap is 2 month, hiring and firing delay is 0.5 month and productivity is 50 dolls per person right.

Now, you finish with dynamic equilibrium; that means, the system should start in a stable state or steady state there has to be no dynamic behaviour that is observed right. So, that will only happen if inventory equals the desired inventory; that means, that inventory value should also be 0; it should also be 1000, the initial value of 1000 is to start modeling dynamic equilibrium.

Now, to get the inventory of 1000 already you know productivity is 50; that means, the number of employees has to be 20. So, now if initial inventory equal to 1000 and initial employee is equal to 20; the system will start in dynamic equilibrium. So, if I start with this condition, system will be dynamic equilibrium.

Now, once you simulate that and verify our model is correct; we can induce oscillations by say for example, introducing an external spike in sales, by say for example, 20 percent increase in sales in week 5. Currently, the sales value is fixed at 1000 per month right; 1000 dolls per month is initial sales value. So, we will see what happens in a 20 percent increase in week 5. So, we will simulate both these scenarios using Vensim.

(Refer Slide Time: 15:19)

Now, let us go to Vensim and open the inventory oscillations model is the exact same model we just saw.

Let us induce a external a spike; there is a 20 percent increase; sudden increase in sales just for one time period that is in time period 5, the sales went 1200 units, after that it fall back to 1000 units. So, if I simulate that model.

(Refer Slide Time: 16:48)

First let us just check what happens to sales; sales just showed 20 percent increase in week 5, then fell back to 1000.

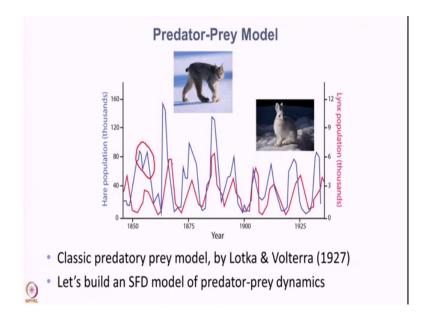

(Refer Slide Time: 17:02)

Let us see what happens to the system in that time yeah. Until week 5, the system is a stable equilibrium, but as soon as an external ah; actually it is an unstable equilibrium as soon as the external force was applied or small perturbation was applied, you can see the immediately the inventory level fell down a bit and then it slowly started to recover..

Just by the inventory level fell down new people are hired, they started producing more inventory and the result was the inventory overshot its target of 1000; inventory is in the Y right side Y axis ah, inventory over shortage target since the inventory was too high; the company started firing people, so, they can produce less, then inventory fell down; lower than the target and as soon as you fell down the target, people started to hire more people and so on and so forth the result in oscillatory behaviour over time. So, these cycles are also; it is a very simplistic model of a business cycle.

(Refer Slide Time: 18:11)

Now, we will look at a model on how to build a system dynamics model of predator prey dynamics. The graph here shows a dynamic behaviour of the predator and prey population over a 100 year time period. On the left side Y axis, we have the population of hare which is nothing, but a prey to this predator which is a lynx which is a kind of a large cat whose population is shown by the red line as per the right side Y axis. As you can see for example, the early part of the graph say in 1850s, you can see here that there is a huge spike in the hare population.

But after some time hare population started to fall; this would be because the prey and the predator that is lynx started to hunt more and more hares as a result of which the hare population started to diminish. As you can see it becomes easier to find their hares right when

there are more hare populations easier to find the prey by the predator hence more were hunted.

The result was there is a natural reduction in the number of hares population which means a predator; that is a predator is going to star which means that there is no more predators to hunt the hares. And then the hare population again started to grow rapidly and as an as it started grow rapidly become easier to find more hares by the predator which results in again hare hunting. And that that resulted in an increase and decrease in a oscillatory fashion or in a cyclic fashion of the both the population of predator as well as the prey. So, this is actually a classical predator prey model like to originally developed by Lotka and Volterra way back in 1920s. Now, we are going to build a SFT model of this predator prey dynamics.

(Refer Slide Time: 20:25)

۲

Predator-Prey Model Assumptions

- Prey population has ample food. Food supply of predator population depends entirely on the size of the prey population.
- · Each prey gives rise to a constant number of offspring per year
- · Each predator eats constant proportion of prey population per year
 - doubling prey population will double the number eaten per predator, regardless of how big the prey population is.
- · Predator reproduction is directly proportional to prey consumed
 - certain number of prey consumed results in one new predator; or that one prey consumed produces some fraction of a new predator.
- · A constant proportion of the predator population dies per year
- predator death rate is independent of the amount of food available

Now, let us look at some basic model assumptions; let us assume that the prey population has ample food; that the food supply of predator population entirely depends on size of the prey population right. Each prey gives rise to a constant number of offspring per year; each predator eats constant proportion of the prey population per year, that is doubling the prey population will double the number eaten per predator regardless of how big the prey population is.

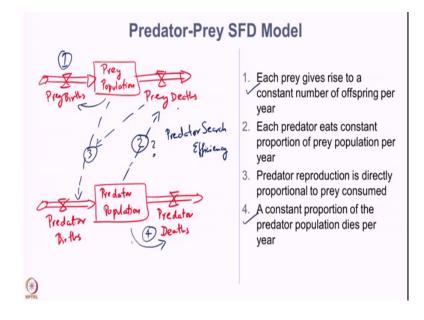

Predator reproduction is directly proportional to prey consume; there is certain number of prey consume results in one new predator or in other words like one prey consume produces some fraction of new predator that is you know you need so many preys to be eaten, so the predator actually survives or the chance of predator to reproduce and the young to survive becomes higher. And we also assume a constant proportion of the predator population dies per year or rather predator death rate is independent of the amount of food available within the system or within the habitat.

(Refer Slide Time: 21:27)

Pre	dator-Pre	ey SFD model
 Stocks 	and	Flows
Prey Population		Prey Birth & Prey Deaths
Predator Population		Predator Births & Predator Douths
<u>@</u>		

The stocks and flows. So, we will start at the very for predator and prey models; the stocks could be the population of each of the species, that is prey population is a stock, predator population will be the stock and both these stocks will be affected by flows.

The prey population is going to be affected by the what it is going to be affected by the prey births and deaths prey births and prey deaths. And predator population is similarly going to be affected by predator births and predator deaths; this will be stocks and flows within our model. (Refer Slide Time: 22:45)

Let us expand a bit here; let us expand it a bit and looking at (Refer Time: 22:52) SFD structure. So, let us draw it; so now we have prey population affected by prey births. And here we have prey deaths, here we have predator population; this will be predator deaths, this will be predator births.

Now, let us look at all the assumptions that we stated a couple of minutes ago. So, first one each prey gives rise to a constant number of offsprings per year. So, this is this is taken care of. So, point one is covered here, the prey population the prey gives rise to a constant number of offspring per year or constant proportion of offsprings per year that can be simply directly captured with some sort of relation like this between the prey population and the prey births.

Now, let us look at the last one the constant proportion of the predator population dies per year. This again can be straight forward and given by this relation between the predator

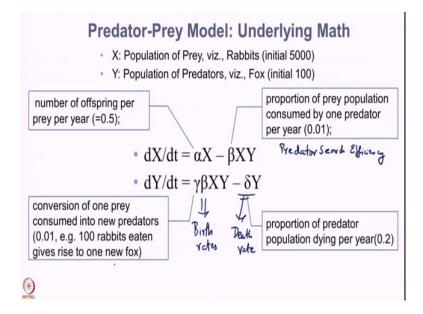

population predator deaths. Now, let us look at to each predator eats constant proportion of prey population per year; so that means, the prey population is somehow affecting the prey deaths.

So, this is what is represented by point number 2; we I have not explicitly captured it we need to capture it in some fashion we will come to that. And in point 3, the predator reproduction is directly proportional to the prey consume; that means, the predator reproduction that is a predators births is a is directly proportional to the amount of prey that they actually eat. So; that means, your prey are affecting how the predators births.

So, this is your scenario number 3; of course, there is something connecting both the deaths as well as the predators births right. Because the prey population does not affect predator births; it is rather the how much predator, how much of the prey is consumed is; what is affects the predators birth right. So, it is actually the number of prey deaths somehow is affecting the predator births through the prey population.

To enable this interaction between the prey and the predator population; we are going to introduce a new term, a new variable in the model called as predator search efficiency; that means, a predator can easily find a prey; then they are going to hunt more if it takes time or difficult to find them prey then; that means, less preys are going to die. Let us see how it connects in the model.

(Refer Slide Time: 27:22)

So, this is a classical model and the underlying math behind it. So, X is the population of the prey and Y is the population of predators. For the model purposes let us assume that preys are the rabbits and the predators are nothing, but foxes; the initial value for rabbit be and initial value of fox be 100.

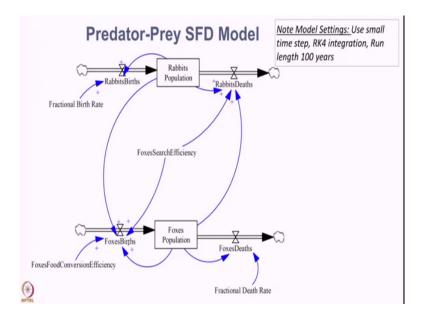

Now, the change in the prey population is affected by let us say dX by dt is alpha X minus beta into XY. So, the first term here represents in both these equations; the first term represents its nothing, but its birth rates and second term represents nothing, but their death rates.

Let us see what these constants represent; alpha is a number of offspring per prey per year, we can take it as 0.5, beta is the proportion of prey population consumed by one predator per year, gamma is the conversion of one prey consumed in to new predators we will again

assume it as 0.01; that is 100 rabbits eaten gives rise to one new fox or rather to sustain one new fox 100 rabbits have to be eaten. Delta is a proportion of predator population dying per year.

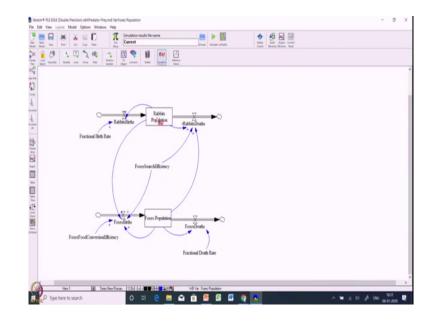

So, now here we have got these; both these represent your birth rates and both these represent the death rates. Delta as it clearly says is the fractional death rate, alpha is a fractional birth rate. Now, beta is a new variable we are looking at called as predator search efficiency and this gamma is a conversion of one prey consume to new predators, we can call it as a kind of conversion efficiency for that. So, let us take a look at how the SDM model or stock flow diagram of the same is going to look like.

(Refer Slide Time: 29:47)

Now, the stock flow is going to look like this; we have the rabbit population, we have the rabbit population, rabbit births, rabbit deaths and a fractional birth rate and foxes search

efficiency which is affecting the foxes birth rate which affects foxes population which affects the foxes deaths. Let us look at some of the and let us now go to Vensim and look at the model.

(Refer Slide Time: 30:30)

Now, let us open Vensim and look at the model. So, predator prey model that we have seen.

The foxes search efficiency is the; you know kind of a fraction or a proportion of the prey; the rather the rabbit that is hunted by the fox per year. So, here it we assumed it to be about 0.01 per fox per year which is quite a low number.

Now, moving on to the fox populations the foxes population again the units of foxes is foxes and initial value is 100.

Foxes death rate is a product of fractional death rate into foxes population, foxes unities foxes per year and fractional death rate is taken as about 0.2 per year; now foxes population is also affected birth rates.

So, foxes birth is affected by 4 parameters, foxes search efficiency multiplied by foxes foot conversion efficiency multiplied by rabbit population multiplied by foxes population.

Now, in this foxes search efficiency multiplied by rabbit population or multiplied by foxes population gives the total number of rabbits death rate right, the total number of rabbits it is consumed. Now, for that total number of rabbits consumed what is the fraction that helps in? A new foxes coming in right; so that is that will get by multiplying the foxes the rabbits death rate by the foxes foot conversion efficiency.

So, that is that foot conversion efficiency is given as 0.01 foxes by rabbits that is per; how many rabbits are required for one fox to sustain and grow. Now, let us simulate this model to see what kind of dynamics we encounter; let us select both the stocks, click graph.

(Refer Slide Time: 33:40)

And we have got a really interesting looking oscillatory behavior between two population of two species of the prey and the predator. The prey or rabbits is a the red and foxes is in the blue; in the left vertical axis is population of foxes and right vertical axis is a population of rabbits.

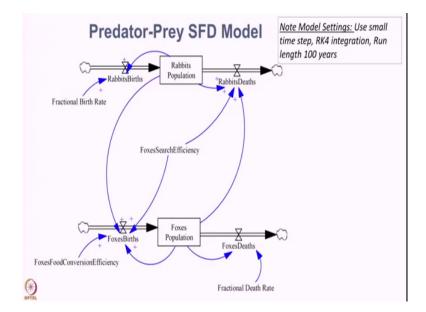

Initially, you can see that the fox population immediately starts to grow and that is at the expense of heavy hunting of rabbit population. The rabbit population starts to diminish really fast as and as you can see as population goes really low it becomes more and more difficult for foxes to find food right; that could be very few rabbits left and it is going to be very difficult to find them in the forest by the foxes.

So, as a result the foxes population also starts to decline; as the foxes population starts to decline; that means, less and less foxes are available to hunt the rabbits; that means, whatever

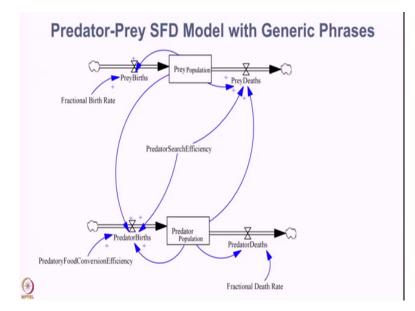

remaining few rabbits are there can sustain and can their population can grow. And rabbits there their population grows faster, they breed much faster as a result the population rapidly explodes to new highs; as more and more rapids are more and more rabbits are available in the forest, the foxes whatever remaining will find food aplenty.

That means, more new foxes can hunt rabbits easily as a result foxes population will also slowly grow after a time lag; after the growth of rabbits population. But as a result when more and more foxes come into play; hunting becomes excessive and the rabbit population again starts to fall down and then which soon follows followed by the fall in the foxes population and so on and so forth.

And so such kind of dynamics is actually common in nature; it is not that the foxes and rabbit population remains stable throughout; in fact, such kind of sinusoidal behavior or oscillatory behavior between the population of two species is actually quite common. (Refer Slide Time: 36:01)

Coming back to the slides; again make note that the model that we simulated used a very small time step RK4 integration and the run length of 100 years.

A classical predator prey model we are I just given the diagram here instead of calling it rabbit and foxes; we can replace it with a very generic terminology is called as a prey and predator in this case, we can extend the model to variety of scenarios. In fact, the prey can actually be grass and the predator could be the say deer or rabbits which eats; eats the grass or prey could be a say deer and a predator could be the lions so on and so forth, but a similar structure for a predator prey population will result in oscillatory behaviour among the predator and the prey population.

Thank you.
