Lecture 49
Single Index Model 1

Welcome back. So, let us continue from where we left off. In the last lecture, I concluded the discussion on the Mean Variance Portfolio Theory which is the cornerstone of contemporary portfolio management. However, if you look at the Mean Variance Portfolio Theory as in fact the learners would have appreciated by now, the calculations are quite cumbersome.

And we now move on to the attempts that have been made in the literature towards simplifying the optimization process and arriving at some kind of a situation where we can implement it practically with lesser problems, lesser difficulties. So, the first model that I am going to discuss is the single index model, and then I will move on to the capital asset pricing model. Finally, I will take up the arbitrage pricing theory which is the contemporary benchmark of modern portfolio theory.

So, let us start with the single index model. Now, to appreciate the backdrop the appreciate to appreciate the background in which this single index model was propounded Harold Markowitz was one of the founders of this model. In fact, Harold Markowitz was awarded the Nobel Prize in 1994 for its mean variance portfolio optimization theory, the complete theory that we discussed in the last few lectures and this is an extension of that in the sense that it is a simplification it is an attempt to use that theory in a more practical environment.

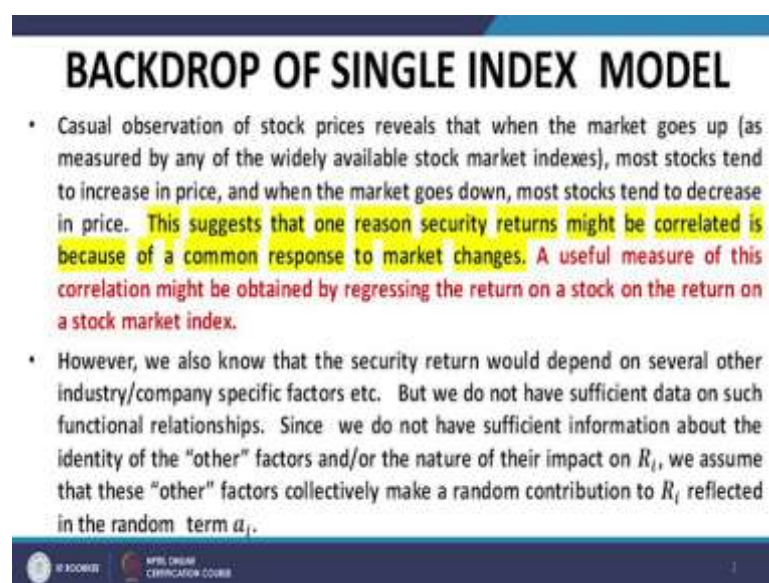

So, you see, the problem arises between why we need to look at simplification processes is because, if you are tracking N assets, N risky assets in your portfolio, then let us understand what are the inputs that we require for formulation of our construction of the optimal portfolio. First of all we need N means or N expected returns of all those N assets and risky assets.

Then we need N variances for each and every one of the risky assets and then we need N into N minus 1 by 2 covariances between the various pairs of securities that are contained in those N risky assets or risky securities. So, we need to track a total of $2n$ plus N into N minus 1 upon 2 parameters to facilitate the optimization process. For example, if N is equal to 100 in other words, if we are tracking 100 securities, the number of parameters that we need to

estimate as inputs to the portfolio optimization using the mean variance optimization framework that we have discussed is the totals to 4750.

And if N is equal to 1000, we will need to track 501 comma 500 parameters which is a gigantic amount and furthermore, the tracking of covariances involve time series analysis of two securities at a time which is even more cumbersome. So, we the amateurs and the practitioners in fact, who were involved in the portfolio optimization practice or trade, attempted to simplify or attempted to find ways of simplifying the situation.

(Refer Slide Time: 04:04)

BACKDROP OF SINGLE INDEX MODEL

- Casual observation of stock prices reveals that when the market goes up (as measured by any of the widely available stock market indexes), most stocks tend to increase in price, and when the market goes down, most stocks tend to decrease in price. This suggests that one reason security returns might be correlated is because of a common response to market changes. A useful measure of this correlation might be obtained by regressing the return on a stock on the return on a stock market index.
- However, we also know that the security return would depend on several other industry/company specific factors etc. But we do not have sufficient data on such functional relationships. Since we do not have sufficient information about the identity of the "other" factors and/or the nature of their impact on R_i , we assume that these "other" factors collectively make a random contribution to R_i reflected in the random term u_i .

© 2008 IIT Bombay NPTEL ONLINE CERTIFICATION COURSE

The first model that was advocated was the single index model, what is the backdrop of the single index model? Casual observations of stock prices reveals that when the market goes up market means market maybe epitomized by a broad-based index like we in India we have the nifty or we have the BSE SNP sent Sensex or some similar index which is representative of the market.

So, it is observed in most cases that stock prices when the market goes up, tend to go up together with the market indices. And similarly, when the market goes down as represented represented by the market indices, most of these stocks tend to go down in prices. So, this is the backdrop of the single index model that there is some intimacy some relationship between the market indices and the stock prices of individual securities.

That forms the backdrop of the single index model. So, the inference that was drawn from this empirical behaviour observed as far as prices of stocks are concerned, or prices of

securities are concerned that the one reason that security returns might be correlated is because of a common response to market changes. So, the interrelationship, intercorrelations between securities, maybe due to their direct correlation or their direct association with a particular market index.

So, when the market changes most of the security change in tandem, although of course, with different amplitudes but the movement tangent, tandem with the origin in the direction of movement of the market indices, and therefore, they seem to be correlated among each other. That is the perception that went into the development of the single index model. And then the the, the advocates of single index, a propounded that a useful measure of this correlation might be obtained by regressing the return on a stock on the return on a stock market index.

This is the backbone of the single index model this particular statement, let me read it again. A useful measure of this correlation might be obtained by regressing the return on a stock on the return on a market index. So, that market index forms the independent variable and the return on the stock forms the dependent variable and if you run a regression between the two with the return on the market index along the x axis and the return on individual securities along the y axis, that the outcome would epitomise the single index model.

So, no, there is there is another issue that I need to highlight in this context, you see the return on a particular security agreed it may relate to the market index, I accept the fact that may relate to the market index. But it would not be totally explained by the market index, there would be some component of the return on the security on an individual security which depends on several other industry or firm's specific factors, which may not be captured by the market index or the relationship between the security and the market index.

But the problem would be that we may not have sufficient data either about the functional relationship between the security returns and these other factors which you may identify as industry factors or firm specific factors. So, what do we do? We do the next best thing that because we do not have sufficient information either about the functional relationship or the data in the context of the exploration of this relationship between the industry or firm specific factors and these individual securities return.

We model all these constituents into one term and we call this a random error term or a random term. So the net result is what of what I am saying trying to say the net takeaway of what I am trying to say is that we can model these individual securities return into two components, we can separate it into two components one is what emanates or what relates to the market variations or the variations in the market index.

Market variations as captured by the market index you may say and the other part which is independent of the market index in which we model as a random term, which encapsulates all of the singular features are in relation to the security like the industry specific or firm specific factors about either about which we do not have much information about the functional relationship between those factors and the and the security return.

Or we do not have enough data to explore there any kind of functional relationship or we are not interested in in, trying to follow up or trying to explore that relationship. In any case, whatever the situation may be, we model these composite factors as a single term as a random term, which contributes to the return on the individual security.

(Refer Slide Time: 09:32)

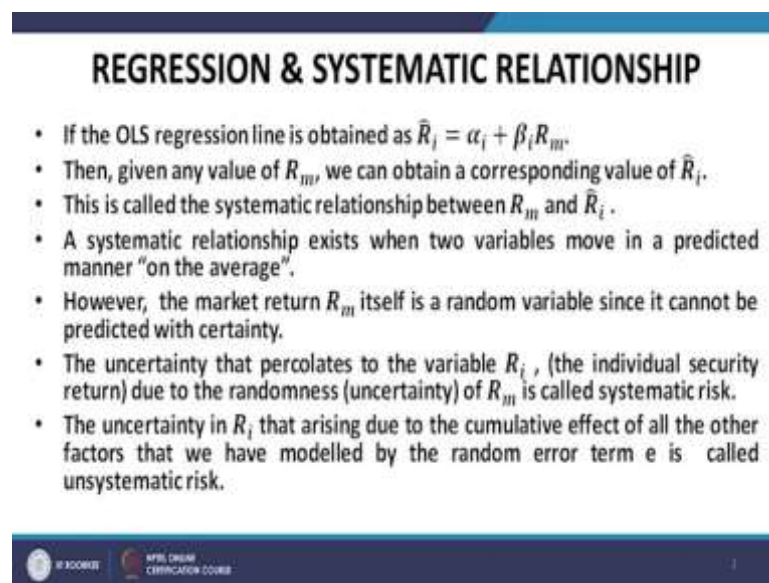

THE SINGLE INDEX MODEL

- **The single index is a statistical regression based empirical model.**
- **The SIM is usually obtained by running a time series regression of the security's returns on the returns on a broad-based market index.**

So, that is, in essence, the philosophy of the single index model. And let us now move on to the development of this model. As I mentioned at the outset, the single index model is a statistical regression based empirical model. I repeat, there is no backdrop theory or finance theory behind the single index model. In fact, this is one aspect which differentiates the single index model from the cap m model.

That we shall discuss after taking up this single index model after completing the single index model. So, the single index model is usually obtained by running a time series regression of the securities return on the returns of a broad-based market index, this is the philosophy of the single index model. Now, if you let me explain certain terms, which would be a which would be taken up again and again during the course of this discussion. So, if you run ordinary least square regression between the security return and the market returns.

(Refer Slide Time: 10:42)

REGRESSION & SYSTEMATIC RELATIONSHIP

- If the OLS regression line is obtained as $\hat{R}_i = \alpha_i + \beta_i R_m$.
- Then, given any value of R_m , we can obtain a corresponding value of \hat{R}_i .
- This is called the systematic relationship between R_m and \hat{R}_i .
- A systematic relationship exists when two variables move in a predicted manner "on the average".
- However, the market return R_m itself is a random variable since it cannot be predicted with certainty.
- The uncertainty that percolates to the variable R_i , (the individual security return) due to the randomness (uncertainty) of R_m is called systematic risk.
- The uncertainty in R_i that arising due to the cumulative effect of all the other factors that we have modelled by the random error term e is called unsystematic risk.

© 2008 IIMB, CHAIR CERTIFICATION COURSE

Let us assume that you get a straight line get represented by our \hat{R}_i is equal to $\alpha_i + \beta_i R_m$. Now, as you can see here, please note \hat{R}_i is different for R_i is different from R_i , I will explain the difference in a minute. But get this by virtue of the regression relationship that we identify by running ordinary least squares regression is that given a value of R_m , we can obtain a corresponding value of \hat{R}_i .

Now, this is called this relationship which arises out of regression is called a systematic relationship between R_m and \hat{R}_i or R_i . So, the OLS regression equation depicts a systematic relationship between the independent variable and the dependent variable. In other words, you can explain the systematic relationship as a relationship that exists between two variables when the two variables move in a predicted manner, predicted maybe by a regression equation.

So, they move in a predicted manner but they move in a predicted manner on the average; this on the average is again to be highlighted and emphasized. Why? Because it is not true that every value of R_i that we get in actual fact on actual observation would be contained or would be captured by this regression equation. Regression equation is the line of best fit as the learners would know.

The regression equation is the line of best fit there would, but the parts that represent actual data need not necessarily at all lie on the regression line totally. Some points maybe above the regression line, some points would be below the regression line, some points will lie on the regression line depending on the nature of data that we have available with us. But the point is, that regression line is the line of best fit and that line of best fit because it is a straight line is captured by this regression, regression equation R_i cap.

Now R_i cap is that point which corresponds to R_m which lies on the regression line. R_i is the point which is the actual value of the data point corresponding to a value of R_m . So, there is a difference between them. Let me repeat R_i cap or R_i hat as the case may be, it represents a point on the regression line which corresponds to R_m . However, R_i itself may be either above R_i cap or R_i , it may be below R_i cap.

But that R_i itself is a dead end actual data point which represents the value that the variable is taking corresponding to the value of R_m . Please note R_i is a random variable because it may take values which are not predetermined which are not predictable and absoluteness. So, there would be difference between R_i cap and R_i that is important. So, this systematic relationship is a relationship between two variables which are captured by a regression line and therefore which move in a predict as predicted by the regression line.

But that that relationship holds on the average that means, if you have a number of observations between the two points, and then the regression relationship would the systematic relationship would tend to predict reasonably good results. But any particular any single value of the actual data may not lie on the regression line may not satisfy this relationship in its absoluteness.

Please note this point this is very fundamental system and to repeat systematic relationship between two variables exist when there is some predictable relationship on the average not for each value. So, this is the this this particular term shall be a backbone in so far as this

single index model and the cap m model is concerned. Now extending on this systematic relationship. R_m itself is also random variable, the market returns are also random variable.

You cannot predict with absolute certainty, what the market return is going to be say two days from now or one day from now or even one hour from now. So, the important thing is that the market returns themselves are random variables. Now, that means, they obviously have a probability distribution and an expected return and a variance. But that is not important at the moment the point is because of this randomness to this random nature of this independent variable R_m certain randomness will percolate down to the value of R_i .

In other words, a certain amount of randomness in R_m will percolate to the dependent variable which is R_i that component of risk or that component of randomness and the corresponding risk that arises from the randomness or the risk of R_m in R_i is termed as systematic risk. Let me repeat the statement it is very important, the uncertainty that percolates to the variable R_i that is the individual securities return due to the randomness or the uncertainty of R_m is called systematic risk.

This again is very important in so far as these models are concerned, the uncertainty in R_i that arises due to the cumulative effect of all other factors, which you have modelled by the random term is called unsystematic risk. So, again we are here we are bifurcating risk into two parts one part of the risk which arises or emanates from the randomness.

The uncertainty the risk embedded in the market returns and being observed in R_i that is called and that is called systematic risk of R_i and the part which arises from other factors which we have modelled by a single random term is called the unsystematic risk and in the security returns R_i .

(Refer Slide Time: 17:05)

THE EXPECTED RETURN UNDER SIM

- The basic SIM equation simply breaks the return on a stock into two components:
- The part due to the market and
- The part independent of the market.
- $R_i = \alpha_i + \beta_i R_m$ (1)
- R_m is the rate of return on the market index—a random variable.
- β_i is a constant that measures the expected change in R_i given a change in R_m .
- α_i is the component of security i 's return that is independent of the market's performance—a random variable.

So, let us now get down to the model itself. The expected return under the single index model, the basic single index model equation simply breaks the return on a stock into two components as I mentioned just now. The part that is due to the market that can be identified as being associated with the market and the part that is independent of the market.

Therefore, we can write R_i as α_i plus $\beta_i R_m$. $\beta_i R_m$ is the part of the return which relates to the market and α_i is the return that is generated by or that is independent from the market and that is generated due to other factors or other terms that are not captured by R_m . So, R_m is the rate of return on the market index and that is a random variable, β_i is a constant that measures the expected change in expected.

Please notice the word expected I highlight emphasize this particular term, we are not talking about actual return we are talking about expected returns. So, β_i is a constant that measures the expected change in R_i given a change in R_m and α_i is a component of securities returns that is independent of the market performance which is again a random variable. So, both R_m and α_i are random variables, both will have a certain probability distribution with means and variances. So, this is the this is the fundamental equation of the single index model.

(Refer Slide Time: 18:39)

DEVELOPMENT OF THE MODEL

- We write
- $a_i = \alpha_i + e_i$ with
- $E(a_i) = \alpha_i$;
- $E(e_i) = 0$
- $R_i = \alpha_i + \beta_i R_m + e_i$ (2)
- Both e_i and R_m are random variables. They each have a probability distribution and a mean and standard deviation.
- For a particular j^{th} realization, we would have:
- $R_{ij} = \alpha_i + \beta_i R_{mj} + e_{ij}$

Now, let us talk about the development of this model we write a_i is equal to $\alpha_i + e_i$, in other words, we split this unsystematic return or this return arising from the random factors industry specific or from specific practice we split it up into the mean of this particular term and the distribution around that mean or the dispersion around it mean and we write it as a_i is equal to $\alpha_i + e_i$ where the expected value of a_i is given by α_i .

And obviously, therefore, the expected value of e_i would be 0 and we can write R_i in this with α_i and e_i embedded incorporated therein in the form of equation 2 as R_i is equal to $\alpha_i + \beta_i R_m + e_i$. Now both now, clearly, the randomness that was there in a_i is not being captured or is not being absorbed by the term e_i and therefore, e_i and R_m continue to be random variables.

And each of them of course, as I mentioned, has a probability distribution and a standard deviation. The j^{th} realization of this particular equation, we will take the form that is given here R_{ij} is equal to $\alpha_i + \beta_i R_{mj} + e_{ij}$.

(Refer Slide Time: 20:12)

ASSUMPTIONS OF THE MODEL

ASSUMPTION 1

$$\text{Cov}(e_i, R_m) = E[(e_i - 0)(R_m - \bar{R}_m)] = 0 \quad (3)$$

- Estimates of α_i , β_i and $\sigma_{e_i}^2$ are often obtained from time series–regression analysis.
- Regression analysis guarantees that e_i, R_m will be uncorrelated, at least over the period to which the equation has been fit.

Now, assumptions about this model. The simplistic version of what the assumptions are, I have already explained let us get into the mathematical representation of those assumptions. The first assumption is that there is no correlation there is no covariance between the term e_i and the R_m that is the two random terms which capture the market risk and the non-market risk are independent of each other.

They do not correlate with each other. This is the fundamental assumption but because we usually develop this model through a regression process, this assumption need not be explicitly made the very fact that we develop this model through regression the process of regression itself captures this assumption or makes this assumption formal into the into the regression process itself.

To repeat the covariance between the unsystematic relationship and the and the systematic relationship that is the two variable e_i and the and R_m are 0 that is they are independent of each other. So, that is equation number 3 and estimates of alpha and beta I have just mentioned this before in fact, estimates of alpha beta and sigma e square are often obtained from time series regression analysis. Regression analysis can guarantees that e_i and R_m will be uncorrelated at least over the period to which the equation has been fit.

(Refer Slide Time: 21:56)

ASSUMPTION 2

- $E(e_i e_j) = 0$ (4)
- This implies that the only reason stocks vary together, systematically, is because of a common co-movement with the market.
- There are no effects beyond the market (e.g., industry effects) that account for co-movement among securities.
- There is nothing in the normal regression method that forces this to be true.
- It is a simplifying assumption that represents an approximation to reality.

IIT BOMBAY FINANCIAL ENGINEERING COURSE

The second assumption is explicit we make this assumption because we need to simplify the remaining part of the model. In other words, to make this model more tractable to make this model fulfil the objective for which it is developed in the first place, that is to simplify the optimization process, we make this additional assumption. What is this additional assumption? The additional assumption is that the expected value of e_i and e_j is equal to 0 that means what?

That means that the only reason that the stocks vary together systematically is because of a common core movement with the market that the any two stocks in the market do not have any internal or have any direct functional relationship or as a result of which they move in tandem, they move in tandem only because of the relationship between stock i and the market and stock j and the market.

Because both these stocks are related systematically to the market, it follows that they would be moving together in some sense and that means, that means what? That means that, if we can afford to on the basis of this assumption rather on the basis of this assumption that the stocks move together only because they are moving along with R_m we can make this assumption that e of expected value of e_i , e_j will be 0.

So, in other words, what we are simply trying to say is there are no effects beyond the market that is industry effects that account for the co-movement among securities. Stocks move together, because they have a relationship with the market or the market index as represented

by the market index. They do not move together because of any direct relationships among themselves that is the underpinning of this particular assumption.

There is nothing in the, this is another issue. There is nothing in the normal regression method that forces this to be true in contrast to the former assumption assumption number 1, which mandated that the covariance between R_m and e_i should be 0. That is there should be uncorrelated which is captured which is a part of the regression assumptions in fact. So, if you are doing this process if you are modelling this as a regression model.

Then that part becomes automatically satisfied or fulfilled. This particular assumption does not get automatically fulfilled, because there is nothing in the normal regression process that forces this to be true. It is a simplifying assumption that represents an approximation to reality. Now, we work out the various parameters relating to the security and the portfolio.

(Refer Slide Time: 25:03)

EXPECTED RETURN & VARIANCE

$$\begin{aligned} \bullet E(R_i) &= E(\alpha_i + \beta_i R_m + e_i) = E(\alpha_i) + E(\beta_i R_m) + E(e_i) \\ \bullet &= E(\alpha_i) + \beta_i E(R_m) + E(e_i) = \alpha_i + \beta_i E(R_m) \end{aligned} \quad (5)$$

$$\sigma_i^2 = E(R_i - \bar{R}_i)^2 \quad \sigma_i^2 = E[(\alpha_i + \beta_i R_m + e_i) - (\alpha_i + \beta_i \bar{R}_m)]^2$$

$$\sigma_i^2 = \beta_i^2 E(R_m - \bar{R}_m)^2 + 2\beta_i E[e_i (R_m - \bar{R}_m)] + E(e_i)^2$$

$$\sigma_i^2 = \beta_i^2 E(R_m - \bar{R}_m)^2 + E(e_i)^2$$

$$\sigma_i^2 = \beta_i^2 \sigma_m^2 + \sigma_a^2 \quad (6)$$

On the basis of the single index model, as far as the expected return is concerned, it is quite straightforward, the expected return on the individual security can be written as alpha i plus beta i into expected return on the market. I repeat, because the expected value of e_i is 0, the expected value of the random error term is 0. Therefore, we directly obtain the expected return on the individual security is equal to alpha i plus beta i expected return on the market this is equation number 5.

As far as the variance of a single security is concerned under the single index model, the derivation is given on the slide it is again a straightforward derivation the sigma square is

given by expected value of R_i minus \bar{R}_i will square when you substitute the value of R_i and \bar{R}_i , \bar{R}_i we have just calculated that is equal to $\alpha_i + \beta_i \bar{R}_m$ and R_i is equal to $\alpha_i + \beta_i R_m + e_i$.

So, when you substitute these values and you do a bit of simplification, the outcome that we arrive at is σ_i^2 is equal to $\beta_i^2 \sigma_m^2 + \sigma_{e_i}^2$ where σ_m^2 is the market variance and $\sigma_{e_i}^2$ is the variance of the random error term. Let me repeat now, you can clearly see that the total risk of the security has been split up into two orthogonal components.

The first component that is related to the market which is captured by the first term $\beta_i^2 \sigma_m^2$ and the second term which is independent of the market will average arises from the other singular factors which we have not considered or which are not an engraved, ingrained in the market and which we represent as the variance of the random error term. So, just like the expected return, we have the variance split up into two parts the expected return error unique part α_i and a market related part $\beta_i R_m$.

Similarly, the variance has the part the unique risk $\sigma_{e_i}^2$ and the market related risk $\beta_i^2 \sigma_m^2$. So, again both the risk and returns are being split up into two components a component which is related to the market which is associated with the market and a component which is independent of the market which is representing the random singular factors to which the return on the security relates.

Now, the covariance of securities as you can see in this in this slide, again is the derivation is quite simple and you have to take keep track of one more particular point that I would like to highlight in this derivation.

(Refer Slide Time: 28:09)

COVARIANCE OF SECURITIES

$$\sigma_{ij} = E[(R_i - \bar{R}_i)(R_j - \bar{R}_j)]$$

$$\sigma_{ij} = E\left\{ \left[\begin{array}{l} [(a_i + \beta_i R_m + e_i) - (a_i + \beta_i \bar{R}_m)] \\ [(a_j + \beta_j R_m + e_j) - (a_j + \beta_j \bar{R}_m)] \end{array} \right] \right\}$$

$$\sigma_{ij} = E(\beta_i (R_m - \bar{R}_m) + e_i)(\beta_j (R_m - \bar{R}_m) + e_j)$$

$$\sigma_{ij} = \beta_i \beta_j E(R_m - \bar{R}_m)^2 + \beta_j E[e_i (R_m - \bar{R}_m)] + \beta_i E[e_j (R_m - \bar{R}_m)] + E(e_i e_j) = \beta_i \beta_j \sigma_m^2 \quad (7)$$

WU ONLINE EMERGENCY COURSE 77

And that is that the expected value of $e_i e_j$ is 0. Please note that this is assumption number 2 of the model that the any 2-security issue or co-movement only because of their common relationship with the market then do not have any direct relationship between them and therefore, the expected value of $e_i e_j$ is equal to 0 and if you use this value, what we end up with is that the covariance between security i and security j is given by beta i, beta j, sigma m square.

I repeat the covariance between security i and security j is given by beta i, beta j, sigma m square. So, the covariance depends only on the market risk in this model as in this this equation or this expression for the covariance clearly justifies our argument that the securities move because of their relationship with the market index and they do not have any direct relationships between themselves.

Because the covariance the covariance term does not contain anything about the individual securities, it contains only the market variance. Thus, the single index model implies that the only reason securities move together is a common response to market movements.

(Refer Slide Time: 29:34)

EXPECTED RETURN OF PORTFOLIO

$$\begin{aligned}\bar{R}_p &= \sum_i X_i \bar{R}_i = \sum_i X_i (\alpha_i + \beta_i \bar{R}_m) \\ &= \sum_i X_i \alpha_i + \left(\sum_i X_i \beta_i \right) \bar{R}_m = \alpha_p + \beta_p \bar{R}_m \quad (8) \\ \text{where } \alpha_p &= \sum_i X_i \alpha_i; \quad \beta_p = \sum_i X_i \beta_i\end{aligned}$$

The expected return of portfolio, this is quite straightforward, I will not devote time to this, this is a replication of the process or the position as far as individual security is concerned. The expected return on a portfolio R_p or R_p bar is equal to alpha p plus beta p R_m bar where alpha p is the weighted average of the alphas of the constituent securities of the portfolio. And beta p is the weighted average betas of the constituent securities of the portfolio.

(Refer Slide Time: 30:45)

VARIANCE OF PORTFOLIO

$$\begin{aligned}\sigma_p^2 &= \sum_i X_i^2 \sigma_i^2 + \sum_i \sum_{\substack{j \\ j \neq i}} X_i X_j \sigma_{ij} \\ \sigma_p^2 &= \sum_i X_i^2 (\beta_i^2 \sigma_m^2 + \sigma_{e_i}^2) + \sum_i \sum_{\substack{j \\ j \neq i}} X_i X_j \beta_i \beta_j \sigma_m^2\end{aligned}$$

The variance of a portfolio well again we have expression which is absolutely akin to the expression that we have for our individual security. Although the derivation is a little bit more involved, we start with the standard expression for the for the variance of a portfolio of

N securities using the mean and the using these variants and the covariance matrix and then on simplification on introducing the expression for the total risk other variance of an individual security given by this expression which I have underlined.

(Refer Slide Time: 31:03)

$$\begin{aligned}
 &= \sigma_m^2 \sum_i X_i^2 \beta_i^2 + \sigma_m^2 \sum_i \sum_{\substack{j \\ j \neq i}} X_i X_j \beta_i \beta_j + \sum_i X_i^2 \sigma_{\epsilon_i}^2 \\
 &= \sigma_m^2 \sum_i \sum_j X_i X_j \beta_i \beta_j + \sum_i X_i^2 \sigma_{\epsilon_i}^2 \\
 &= \sigma_m^2 \sum_i (X_i \beta_i) \sum_j (X_j \beta_j) + \sum_i X_i^2 \sigma_{\epsilon_i}^2 = \beta_p^2 \sigma_m^2 + \sum_i X_i^2 \sigma_{\epsilon_i}^2 \quad (9)
 \end{aligned}$$

And further simplification we end up with the expression that is given in equation number 9. Beta p square sigma m square this is the systematic risk and summation sigma Xi square sigma ei square This is the unsystematic risk. Let me repeat beta p square sigma m square represents the systematic risk of the portfolio and summation of Xi square sigma ei square represents the unsystematic risk of the portfolio.

Thus, the total variance of the portfolio is again orthogonally divided into two parts. One part the systematic part are arising from the market totally from the market which is captured by the first term and the second part arising from the singular random variable or the singular term which captures the other factors.

So, I repeat the total variance is split up into two orthogonal parts beta p square sigma m square, which represents the randomness arising out of the market randomness and the other term arising from intrinsic randomness of the security.

(Refer Slide Time: 32:03)

SYSTEMATIC & UNSYSTEMATIC RISK

The variance of an N security portfolio is :

$$\sigma_p^2 = \sum_{j=1}^N (X_j^2 \sigma_j^2) + \sum_{j=1}^N \sum_{\substack{k=1 \\ k \neq j}}^N (X_j X_k \sigma_{jk})$$

If the portfolio is equally weighted in all securities, then

$$\sigma_p^2 = \sum_{j=1}^N \left(\frac{1}{N}\right)^2 \sigma_j^2 + \sum_{j=1}^N \sum_{\substack{k=1 \\ k \neq j}}^N \left(\frac{1}{N}\right)^2 \sigma_{jk}$$

WUOL ONLINE EMPOWERMENT COURSE 33

So, I just mentioned that $\beta_p^2 \sigma_M^2$ represents the system systematic risk and the other term $\sum X_i^2 \sigma_{ei}^2$ represents the unsystematic risk. Let us explore that this a little bit more, let us assume we know that the variance of an N security portfolio is given by this expression here on this slide. Let us assume that we have a portfolio which is equally weighted in all security and money amounts.

I repeat, we will start with the formula for the variance of an N security portfolio which is given by the first equation on the slide and then we assume that this portfolio that we are considering consists of equal weights of each of the constituent securities. So, for all the securities are equally constituted equally included in terms of money values, in terms of money values in the given portfolio.

So, the weight of each security will begin by $1/N$ because there are N securities and let us assume that the weight and the total value of investment is 1 unit. So, the amount of investment in each security will be equal to $1/N$. So, then we if we substitute X_1 equal to X_2 equal to X_3 for all X's, we substitute $1/N$ we arrive at this second equation on this slide.

(Refer Slide Time: 33:32)

$$\sigma_P^2 = \left(\frac{1}{N}\right) \left(\frac{\sum_{j=1}^N \sigma_j^2}{N}\right) + \left(\frac{N-1}{N}\right) \left[\frac{\sum_{j=1}^N \sum_{\substack{k=1 \\ k \neq j}}^N \sigma_{jk}}{N(N-1)}\right]$$

$$\sigma_P^2 = \frac{1}{N} \bar{\sigma}_j^2 + \left(\frac{N-1}{N}\right) \bar{\sigma}_{jk} \Rightarrow \text{Lim}_{N \rightarrow \infty} \sigma_P^2 = \bar{\sigma}_{jk}$$

Now, the second equation that was there on the previous slide can be written in this form that is here as the first equation. In the first term, we have taken 1 upon N outside and we have written the first term that represents the intrinsic variance of the securities divided by N and the second term relates to the covariances. Now, if you look carefully, let us analyse the first term first.

The first term in the numerator contains sigma of summation of sigma square in other words, it is the sum of the variances of all the securities. Sum of the variances of all the securities and it has been divided by the number of security. So, in some sense, you can take it as the average variance of the of the portfolio or average variance or the various per security or the average variance for security of the portfolio.

That is the first term. Now, if you look at the second term, the second term in the numerator contains the summation of all covariances. Please note given N securities the number of covariances are N into N minus 1 although the number of unique covariances will be N into N minus 1 upon 2 because sigma ij is equal to sigma ji for any pair of securities, but the total number of covariances which include non-distinct covariances will be equal to N into N minus 1.

So, the the numerator in this term represent the sum of all the covariances and the denominator represents the number of covariances. So, we are dividing the sum of all covariances by the number of covariances. And what we get therefore is in some sense the

average covariance. So, the first term already gives us the average variance per security and the second term gives us the average covariance.

Now, let us look at how the situation develops when we increase the number of securities in the portfolio. If we take the limit of this expression σ_p^2 in the form that we have written it in the first equation, as N tends to infinity, what we get is, we get limit and tending to infinity σ_p^2 is equal to $\bar{\sigma}_{JK}$ that is the first term will disappear will tend to 0 because of the free factor of $1/N$ as N tends to infinity, the prefactor will tend to 0 and therefore, the first term will vanish.

What about the second term if you look carefully, $(N-1)/N$ in the limit that N tends to infinity is equal to 1 and therefore, the second term does not vanish, the second term remains intact when even in the situation where N tends to infinity. So, the net outcome is that even after infinite diversification, we have a situation where one of the components of risk the component of risk that arises from the variances does disappear.

The component of the risk that arises from mutual covariances does not disappear and the part that disappears is called diversifiable risk or unsystematic risk and the part that does not disappear, which arises from mutual co correlations or mutual interactions is the part that does not disappear and it is called undiversifiable risk or systematic risk. So, the outcome of this particular exposition is summarized in this slide.

INFERENCES

- There is some part of the total risk of a portfolio that can be diversified away.
- This component of risk arises from the intrinsic variances of the individual securities.
- The component of risk that is non-diversifiable emerges from mutual co-relations between securities.

Let us read through it, there is some part of the total risk of a portfolio that can be diversified away the first component that was part of the equation the first term of the equation, the component of the is this component of the risk arises from the intrinsic variances of individual securities. This is the unsystematic risk it arises from the individual variances of the securities and the component of risk that is non diversifiable that is systematic risk arises from mutual correlations between the securities. So, we shall continue from here after the break. Thank you.
