Numerical Differentiation

Last time we have considered Romberg integration. Today, we are going to show that first step in the Romberg integration is nothing but Simpson's rule; so we assume that our function f is four times differentiable. We look at corrected composite trapezoidal rule; in the corrected composite trapezoidal rule, when we remove or get rid of the term x square that is the first step of Romberg integration and that first step gives us Simpson's integration.

(Refer Slide Time: 01:05)

Romberg Integration

$f \in C^4 [a, b]$

$a = t_0 < t_1 < \dots < t_n = b, \quad h = \frac{b-a}{n}, \quad n: \text{even}$

$T_n = \frac{h}{2} (f(a) + f(b)) + h \sum_{i=1}^{n-1} f(t_i) : \text{Composite Trapezoidal Rule}$

$\int_a^b f(x) dx = T_n + \frac{h^2}{12} (f'(a) - f'(b)) + O(h^4)$

$\int_a^b f(x) dx = T_{\frac{n}{2}} + \frac{(2h)^2}{12} (f'(a) - f'(b)) + O(h^4)$

$T_h^1 = \frac{4T_n - T_{\frac{n}{2}}}{3} \quad \int_a^b f(x) dx = T_h^1 + O(h^4)$

So, our function f is four times continuously differentiable; we look at a uniform partition of interval a, b . So, t_0, t_1, t_n these are equidistant points; h is length of a sub interval which is going to be b minus a by n and in addition let us assume that n is even.

Composite trapezoidal rule associated with this partition is given by, at two end points the weight is h by 2 . So, h by 2 $f(a)$ plus $f(b)$ and at the interior partition points, that means,

t_1, t_2, \dots, t_{n-1} the weight is going to be h . So, this is the composite trapezoidal rule. Now, $\int_a^b f(x) dx = T_n + \text{term } h^2 \text{ by } \frac{1}{12} (f(a) - f(b)) + \text{term of the order of } h^4$. If you look at $\frac{1}{12} (f(a) - f(b))$, there is no h coming into picture; so this term is independent of the partition. Now, you look at composite trapezoidal rule with partition of the length of the subinterval, let it be $2h$ and number of subintervals let them be $n/2$.

So, $\int_a^b f(x) dx = T_{n/2} + h^2 \text{ will be replaced by } \frac{1}{12} (f(a) - f(b)) + \text{term of the order of } h^4$, but in the order the constant is there. So, we can say that it is of the order of h^4 .

The first step of Romberg integration is obtained by multiplying this equation by 4, subtracting this equation and dividing throughout by 3. And we have seen that $\int_a^b f(x) dx = T_{n/2} + \text{term of the order of } h^4$.

So, now we are going to look at $T_{n/2}$ and show that this $T_{n/2}$ is nothing but Simpson's rule associated with the partition with $n/2$ intervals and length to be equal to $2h$. So, it is a straight forward calculation, but what it shows is, when you have f to be sufficiently differentiable, $\int_a^b f(x) dx - T_n$; T_n is the composite trapezoidal rule, we have got asymptotic series expansion with the terms of the type $c_1 h^2 + c_2 h^4 + c_3 h^6 + \dots$ and so on. So, we have got only even degrees of h . Now, once we show that the first step of Romberg integration is nothing but the Simpson integration that will mean that even for composite Simpson integration we have got this asymptotic series expansion. So, now let us look at $T_{n/2}$.

(Refer Slide Time: 04:45)

$$T_n = \frac{h}{2} (f(a) + f(b)) + h \sum_{i=1}^{n-1} f(t_i)$$

$$T_{\frac{n}{2}} = h (f(a) + f(b)) + 2h \sum_{\substack{i=2 \\ i \text{ even}}}^{n-2} f(t_i)$$

$$T_n^1 = \frac{4T_n - T_{\frac{n}{2}}}{3} = \frac{h}{3} (f(a) + f(b)) + \frac{4h}{3} \sum_{\substack{i=1 \\ i \text{ odd}}}^{n-1} f(t_i) + \frac{2h}{3} \sum_{\substack{i=2 \\ i \text{ even}}}^{n-2} f(t_i)$$

Simpson Rule

So, our t_n is given by this formula in T_n by 2; T_n by 2 will consist of points t_0, t_2, t_4, t_6 and t_n only even order points. So, T_n by 2 will be h times $f(a) + f(b)$; the length of subinterval now it is going to be t_0 to t_2 , so that is going to be $2h$. So, it will be plus $2h$ and now only even **suffix as**. So, it will be summation i goes from 2 to n minus 2 i even $f(t_i)$; our T_n^1 is 4 times T_n minus T_n by 2 divided by 3. So, here you are **you** are multiplying by 4 and then subtract it. So, that will give you h by 3 $f(a) + f(b)$ plus odd terms they are going to come only from here.

So, that is why you have $4h$ by 3 summation i goes from 1 to n minus 1 i odd $f(t_i)$ plus there are even order terms here, even order terms here, you are multiplying this by 4 and then subtracting this and dividing by 3. So, that is why you get $2h$ by 3 summation i goes from 2 to n minus 1 $f(t_i)$, i even.

So, see our partition now is $t_0, t_2, t_4, t_6, t_n, t_1, t_3, t_5$ these are going to be midpoints of our interval and if you look at composite Simpson rule associated with partition t_0, t_2, t_4 it is nothing but this. So, thus we have shown that the first step of Romberg integration gives us composite Simpson rule.

Now, we are going to start a new topic which is numerical differentiation. The idea is similar as in the case of numerical integration. In order to integrate, **we had** we do not know how to integrate any continuous function. So, we look at interpolating polynomial, integrate it; so, there is some error involved; so we obtained approximation.

So, similar thing we are going to do here, that if you have a polynomial, then you can differentiate. So, approximate your function f by a polynomial and then, hope that the derivative of polynomial at some point say a , that will give you an approximation to f' at a . Now, in numerical differentiation, we will face some difficulties which we did not face in case of numerical integration.

Numerical differentiation which I am going to describe now, which allows us to find an approximation to the derivative f' at a or the second derivative or higher order derivative, these formulae they are important in solution of differential equations. So, approximate solution of differential equations when one considers that is where we are going to use this formula.

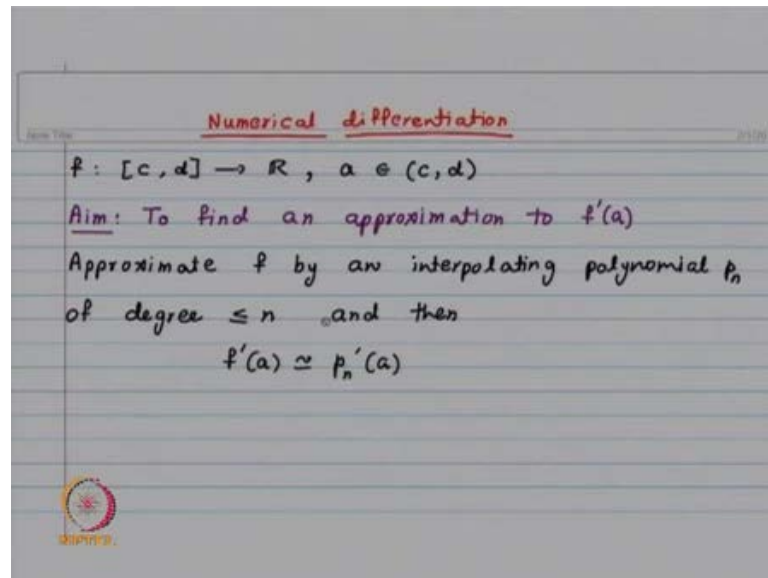

As **said as** I said there is going to be some difficulty in the numerical differentiation rule, suppose you want to find f' at a then what should be done? So, instead of interpolating polynomial what one should do is, look at some different polynomial approximation, say look at g^2 approximation by polynomials. So, that part we haven't considered so far, but we have considered cubic spline interpolation. So, instead of interpolating polynomial look at cubic spline interpolation of your function.

So, in the cubic spline interpolation what we did was, we looked at interval a, b , sub divided into equal subintervals and then, we try to fit a piecewise cubic function. So, on each subinterval our function was a cubic polynomial or a polynomial of degree less than or equal to 3 and at the partition points, because **now we have got...** look at the two subinterval; so on one interval you have got the polynomial of degree less than or equal to 3; on another it is another polynomial of degree less than or equal to 3. So, we want that both of them, they should join at in such a manner that over all we have got two times differentiable function. So, that give raise to a tri-diagonal system to solve and then we could obtain a cubic piecewise cubic polynomial, which is overall two times differentiable, which interpolates the given function at the partition points and in addition we had two end point.

So, this cubic spline interpolation it gives acceptable approximation to the derivative of function. But today what we are going to do is, we are going to look at our interpolating polynomial of appropriate order and get the derivatives and see what is the difficulty one faces in case of numerical differentiation. We are going to slightly make change

notation; the only change is our function earlier, it was defined on interval a, b . So, we will say that it is defined on interval c, d and a will be interior point of our interval. So, our aim is to find approximation to f' of a .

(Refer Slide Time: 11:41)

So, f is from c, d to \mathbb{R} real valued function a is interior point. Aim is to approximate f' of a . So, approximate f by an interpolating polynomial p_n of degree less than or equal to n and f' of a is approximately equal to p'_n of a . The simplest case is going to be take n is equal to 0, that means approximate your function by a constant polynomial.

So, the derivative is going to be 0. So, then you get an approximation, but that is not really a very accurate approximation. So, instead of n is equal to 0, let us look at n is equal to 1, that means x_0 and x_1 we are going to choose two interpolation points, fit a polynomial of degree less than or equal to 1 and then its derivative will give you approximation to f' of a . And the starting point is going to be function $f(x)$ is equal to interpolating polynomial plus an error, take the derivative, the derivative of the polynomial will give you approximation to f' of a and this approximation will depend, which interpolation points you are going to choose. So, our interpolation points x_0 and x_1 , they will give rise to two formulae which we are going to consider.

So, in one case, we are trying to approximate f' of a . So, x_0 and x_1 , the points which you are taking as interpolation points it's logical that you should choose them in the vicinity of point a . So, suppose I choose x_0 is equal to a , and x_1 to be equal

to a plus h, where h is going to be a small number. So, that will give us a formula, which is known as forward difference formula and another formula, which we are going to consider there instead of choosing the points to be a and a plus h, we will try to choose our points symmetrically.

So, a is the point at which we **found** want to find the derivative. So, we can choose point to be say a minus h and a plus h and then, we will see which one gives us a better error estimate.

(Refer Slide Time: 14:35)

x_0, x_1 : distinct points in $[c, d]$

$$p(x) = \underbrace{f(x_0) + f[x_0, x_1](x-x_0)}_{p_1(x)} + \underbrace{f[x_0, x_1, x](x-x_0)(x-x_1)}_{w(x)}$$

$$p'(x) = p_1'(x) + \frac{d}{dx} \{ f[x_0, x_1, x] w(x) \}$$

$$= f[x_0, x_1] + \left[\frac{d}{dx} f[x_0, x_1, x] \right] w(x) + f[x_0, x_1, x] w'(x)$$

x_0 and x_1 are distinct points in c, d . $f(x)$ is equal to $f(x_0)$ plus divided difference based on x_0, x_1 into $x - x_0$ and then, this is the error term, the divided difference based on x_0, x_1, x multiplied by $w(x)$; $w(x)$ is $(x - x_0)(x - x_1)$, take derivative of both the sides. So, you will have $f'(x)$ is equal to $p_1'(x)$ plus derivative of this error, term $p_1'(x)$ will be nothing but divided difference based on x_0, x_1 plus you apply a product rule. So, you get d/dx of $f[x_0, x_1, x]$ multiplied by $w(x)$ plus the divided difference into $w'(x)$ the divided difference $f[x_0, x_1, x]$ is going to provide approximation to $f'(x)$ and this is an error term. So, in the error term, derivative of the divided difference x_0, x_1, x is appearing.

We have already seen continuity of divided differences; if your function f is once differentiable, then the divided difference based on x_0, x_1, x this is a continuous function; you are assuming x_0 and x_1 to be distinct point. So, this part we have already

seen; now we are going to show that if f is twice differentiable, then the derivative of the divided difference based on x_0, x_1, x is going to be a divided difference based on points x_0, x_1, x, x . So, this result now we will first prove, so that we can estimate our error in numerical differentiation.

(Refer Slide Time: 17:05)

The image shows a handwritten proof on a slide. At the top, a box contains the claim: $\frac{d}{dx} f[x_0, x] = f[x_0, x, x]$. Below this, the proof begins with "Proof:" and "Let $g(x) = f[x_0, x] = \begin{cases} \frac{f(x) - f(x_0)}{x - x_0}, & x \neq x_0 \\ f'(x_0), & x = x_0 \end{cases}$ ". Then, for $x \neq x_0$, the derivative is calculated as $g'(x) = \frac{(x - x_0)f'(x) - [f(x) - f(x_0)]}{(x - x_0)^2} = \frac{f'(x) - f[x_0, x]}{x - x_0} = f[x_0, x, x]$. A small logo is visible in the bottom left corner of the slide.

So, first we look at divided difference based on x_0 and x ; x_0 is going to be a fix point. So, this g , I define g of x to be equal to divided difference based on x_0 and x , which is going to be equal to $f(x) - f(x_0)$ divided by $x - x_0$, if x not equal to x_0 ; and equal to $f'(x_0)$, if x is equal to x_0 . So, this is my function g and I want to find $g'(x)$; there will be two cases x not equal to x_0 , and x is equal to x_0 .

When x is not equal to x_0 , we **have to** we have a quotient of two functions. So, we will use standard formula for calculating the derivative; when our point x is equal to x_0 , then our function g is defined differently at x_0 , it is $f'(x_0)$; at x not equal to x_0 , it is the quotient $f(x) - f(x_0)$ divided by $x - x_0$.

So, when I want to calculate the derivative of g at x_0 , I will have to go from the definition; I will have to proceed from the definition, that $g'(x_0)$ will be limit as h tends to 0 of $g(x_0 + h) - g(x_0)$ divided by h .

So, we will consider these two **[speech/special]** separate cases and show that the derivative of divided difference based on x_0, x is nothing but the divided difference based on x_0, x, x .

(Refer Slide Time: 19:12)

The image shows a handwritten mathematical proof on a slide. At the top, a claim is boxed: $\frac{d}{dx} f[x_0, x] = f[x_0, x, x]$. Below this, the word "Proof:" is written. The next line defines $g(x) = f[x_0, x]$ as a piecewise function: $\frac{f(x) - f(x_0)}{x - x_0}$ for $x \neq x_0$ and $f'(x_0)$ for $x = x_0$. Then, for $x \neq x_0$, the derivative $g'(x)$ is calculated using the quotient rule: $\frac{(x - x_0)f'(x) - [f(x) - f(x_0)]}{(x - x_0)^2}$. This is then simplified to $\frac{f'(x) - f[x_0, x]}{x - x_0}$, which is equal to $f[x_0, x, x]$. A small logo is visible in the bottom left corner of the slide.

So, first the case x not equal to x_0 ; $g'(x)$ will be x minus x_0 square, then denominator multiplied by derivative of the numerator x_0 is fixed. So, it is $f'(x)$ minus numerator $f(x) - f(x_0)$ and then the derivative of the denominator that is going to be 1.

Now, one $x - x_0$ we cancel; so we will have $f'(x)$ upon $x - x_0$; here one $x - x_0$ we associate with $f(x) - f(x_0)$. So, $f(x) - f(x_0)$ divided by $x - x_0$ that gives us divided difference of f based on x_0, x .

Now, this is nothing but the divided difference based on x_0, x, x that is the recurrence formula; this is nothing but divided difference of f based on x comma x . So, that is $f'(x)$ minus divided difference based on these two points and divided by $x - x_0$. So, we have proved the claim for x not equal to x_0 . Now, look at x is equal to x_0 and apply the definition.

(Refer Slide Time: 20:41)

$$g(x) = f[x_0, x] = \begin{cases} \frac{f(x) - f(x_0)}{x - x_0}, & x \neq x_0 \\ f'(x_0), & x = x_0. \end{cases}$$

Consider $\frac{g(x_0+h) - g(x_0)}{h} = \frac{f[x_0, x_0+h] - f'(x_0)}{h}$

$$= \frac{f(x_0+h) - f(x_0) - h f'(x_0)}{h^2} = \frac{h^2 f''(c)}{h^2}, \quad c \text{ between } x_0 \text{ and } x_0+h$$

$$\rightarrow \frac{f''(x_0)}{2} = f[x_0, x_0, x_0] \text{ as } h \rightarrow 0.$$

Thus $g'(x_0) = \lim_{h \rightarrow 0} \frac{g(x_0+h) - g(x_0)}{h} = f[x_0, x_0, x_0]$

So, consider $g(x_0+h) - g(x_0)$ divided by h , this is going to be equal to by our definition of $g(x)$ it will be $f(x_0+h) - f(x_0)$ minus $h f'(x_0)$ divided by h^2 . This quotient is nothing but $f(x_0+h) - f(x_0) - h f'(x_0)$ divided by h^2 . We are assuming function to be two times differentiable. So, for the numerator, we can apply extended mean value theorem.

So, that extended mean value theorem gives us numerator to be equal to h^2 by $2 f''(c)$ and then this h^2 , where c going to be lie between x_0 and x_0+h ; our h can be bigger than 0 or less than 0. So, our c will be in the interval x_0 to x_0+h , if h is bigger than 0 or it will be in the interval x_0+h to x_0 , if h is less than 0. Now, we are going to let h tend to 0. So, when h tends to 0, c which lies between x_0 and x_0+h , that will tend to x_0 .

(Refer Slide Time: 22:32)

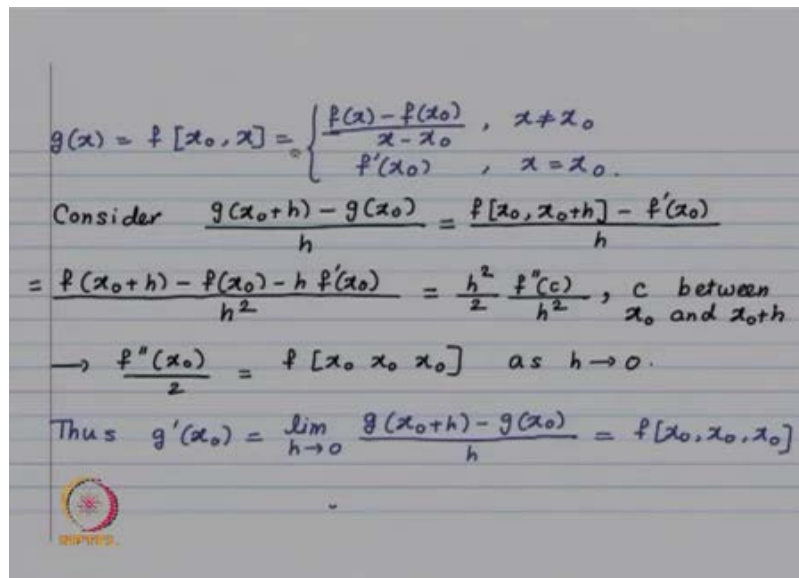

$$g(x) = f[x_0, x] = \begin{cases} \frac{f(x) - f(x_0)}{x - x_0}, & x \neq x_0 \\ f'(x_0), & x = x_0. \end{cases}$$

Consider $\frac{g(x_0+h) - g(x_0)}{h} = \frac{f[x_0, x_0+h] - f'(x_0)}{h}$

$$= \frac{f(x_0+h) - f(x_0) - h f'(x_0)}{h^2} = \frac{h^2}{2} \frac{f''(c)}{h^2}, \quad c \text{ between } x_0 \text{ and } x_0+h$$

$$\rightarrow \frac{f''(x_0)}{2} = f[x_0, x_0, x_0] \text{ as } h \rightarrow 0.$$

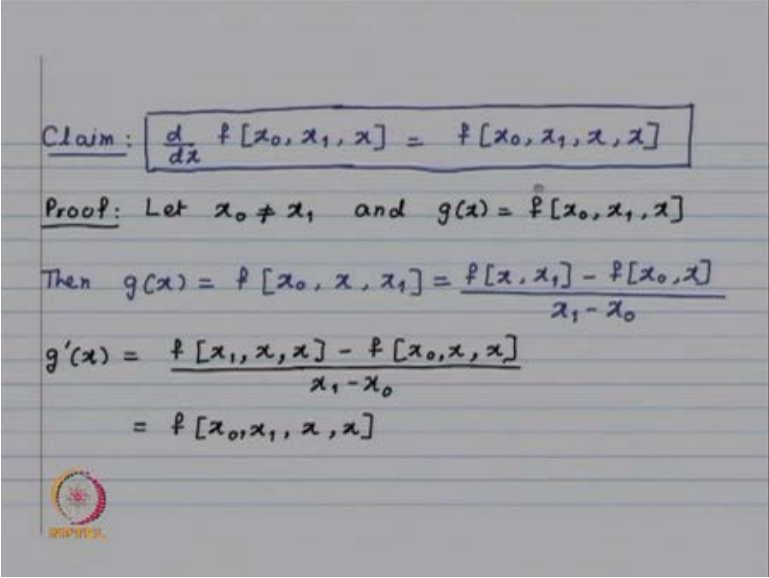

Thus $g'(x_0) = \lim_{h \rightarrow 0} \frac{g(x_0+h) - g(x_0)}{h} = f[x_0, x_0, x_0]$

And using that we get the $f''(c)$ by 2, that will be tending to $f''(x_0)$ by 2 which by definition of divided difference is f divided difference of f based on x_0, x_0, x_0 ; x_0 repeated thrice and thus $g'(x_0)$ is f of x_0, x_0, x_0, x_0 . We had already proved that $g'(x)$ is the divided difference of f based on x_0, x, x and now that formula is valid for x is equal to x_0 . Now, what we wanted was the derivative of divided difference based on x_0, x_1, x , because that is what comes into picture in the linear approximation. We have proved that the divided difference of $f(x_0, x)$ its derivative is nothing but add 1 extra.

So, now, let us look at the divided difference based on x_0, x_1, x and try to find its derivative. So, x_0 and x_1 , these are distinct points. You look at $f(x_0, x_1, x)$, our divided difference is symmetric about its arguments that mean the order of x_0, x_1, x will not matter. So, the divided difference based on x_0, x_1, x will be same as divided difference based on x_0, x, x_1 .

(Refer Slide Time: 24:18)

Claim: $\frac{d}{dx} f[x_0, x_1, x] = f[x_0, x_1, x, x]$

Proof: Let $x_0 \neq x_1$ and $g(x) = f[x_0, x_1, x]$

Then $g(x) = f[x_0, x, x_1] = \frac{f[x, x_1] - f[x_0, x]}{x_1 - x_0}$

$$g'(x) = \frac{f[x_1, x, x] - f[x_0, x, x]}{x_1 - x_0}$$
$$= f[x_0, x_1, x, x]$$

So, now our $g(x)$ is divided difference based on x_0, x, x_1 by recurrence formula this is $f[x_1, x, x] - f[x_0, x]$ divided by $x_1 - x_0$.

And now, we want look at the derivative of this denominator is constant derivative of $f[x_1, x, x]$ will be nothing but add $1/x$ extra. So, it is going to be $f[x_1, x, x]$ minus $f[x_0, x, x]$ divided difference derivative of f of x_0, x, x and then, divide by $x_1 - x_0$. So, again by the recurrence formula, we get $g'(x)$ to be the divided difference based on x_0, x_1, x, x . So, that proves our claim.

And now, we go back to our formula for finding approximate value of $f'(a)$. So, our function f is defined on interval $[c, d]$ takes real values; a is an interior point; x_0 and x_1 are two distinct points in the interval $[c, d]$; we are fitting a polynomial of degree 1 and then, we have got error term, you differentiate both the side.

(Refer Slide Time: 26:05)

Forward Difference Formula

Let $f: [c, d] \rightarrow \mathbb{R}$ and $x_0, x_1 \in [c, d], x_1 \neq x_0$.

$$f(x) = f(x_0) + f[x_0, x_1](x - x_0) + \frac{f[x_0, x_1, x](x - x_0)(x - x_1)}{w(x)}$$

$$f'(x) = f[x_0, x_1] + f[x_0, x_1, x]w(x) + f[x_0, x_1, x]w'(x)$$

$$w'(x) = x - x_0 + x - x_1$$

Let $x = x_0 = a, x_1 = a + h$. Then $w(a) = 0, w'(a) = -h$

$$f'(a) \approx f[a, a+h] = \frac{f(a+h) - f(a)}{h},$$

$$\text{error} = f[a, a+h, a](-h) = -\frac{h^2 f''(c)}{2}$$

So, $f(x)$ is equal to $f(x_0)$ plus $f[x_0, x_1](x - x_0)$ and this is the error term. So, the error term has this divided difference and our function $w(x)$ take the derivative of both the sides; $f(x_0)$ is constant. So, $f'(x)$ will be equal to divided difference $f[x_0, x_1]$ plus now the derivative of these we know that it is nothing but add one extra x ; so, it will be $f[x_0, x_1, x]$ multiplied by $w(x)$; we are applying product rule plus $f[x_0, x_1, x]$ into $w'(x)$; $w'(x)$ will be nothing but $x - x_0$ plus $x - x_1$.

So, now, we want to choose our x_0 and x_1 . So, we are going to choose them in the vicinity of our point a . So, the first case is choose x_0 to be equal to a , and x_1 is equal to $a + h$.

(Refer Slide Time: 27:16)

Forward Difference Formula

Let $f: [c, d] \rightarrow \mathbb{R}$ and $x_0, x_1 \in [c, d], x_1 \neq x_0$.

$$f(x) = f(x_0) + f[x_0, x_1](x-x_0) + f[x_0, x_1, x] \underbrace{(x-x_0)(x-x_1)}_{w(x)}$$

$$f'(x) = f[x_0, x_1] + f[x_0, x_1, x, x]w(x) + f[x_0, x_1, x]w'(x)$$

$$w'(x) = x-x_0 + x-x_1$$

Let $x = x_0 = a, x_1 = a+h$. Then $w(a) = 0, w'(a) = -h$

$$f'(a) \approx f[a, a+h] = \frac{f(a+h) - f(a)}{h},$$

$$\text{error} = f[a, a+h, a](-h) = -\frac{h f''(c)}{2}$$

So, when you do that, our $w(x)$ is $(x - x_0)(x - x_1)$; x is equal to x_0 is equal to a . So, $w(a)$ is going to be equal to 0 and $w'(a)$ will be this will be $-h$; this will be **a minus** a minus h . So, it is a minus h .

Now, $f'(a)$ is approximately equal to divided difference based on a , and $a+h$ which is $\frac{f(a+h) - f(a)}{h}$. And the error is going to be equal to $w'(a)$ is 0; so, there will be no contribution from this term; so it will be only from here. So, it will be $f[a, a+h, a]$ into $-h$. Now, function f , because it is two times differentiable, it will be $-\frac{h f''(c)}{2}$. So, in fact, this c it should be something say $f''(\psi)$; this c and this c , they are not the same; it is $-\frac{h f''(\psi)}{2}$. So, this is discretization error and this is known as forward difference formula.

So, now, let us look at the case when you choose your two interpolation points symmetrically. So, our point will be $a-h$, and $a+h$ and we will see that in this case the discretization error is going to be of the order of h^2 . So, for forward difference, we had only the error to be less than or equal to constant times h ; it will be now less than or equal to constant times h^2 .

(Refer Slide Time: 29:17)

Central Difference Formula

$$f'(x) = f[x_0, x_1] + f[x_0, x_1, x, x]w(x) + f[x_0, x_1, x]w'(x)$$
$$w(x) = (x-x_0)(x-x_1), \quad w'(x) = x-x_0 + x-x_1$$

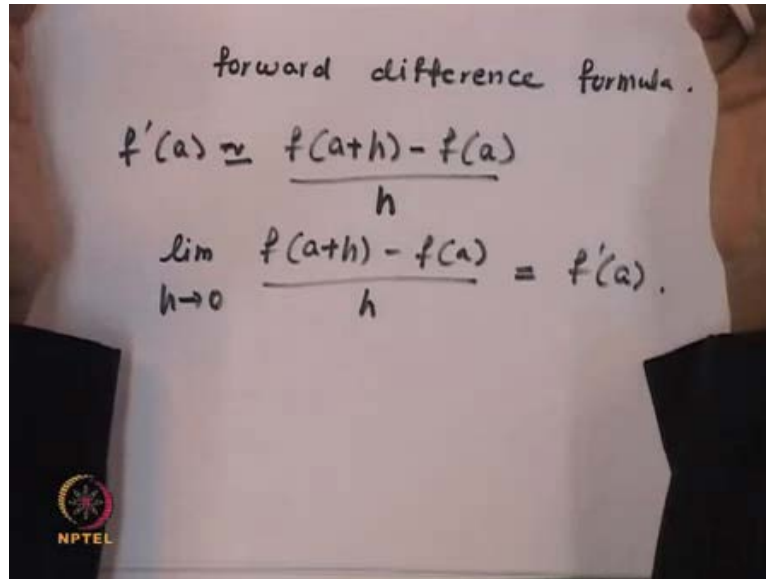

Let $x = a$, $x_0 = a-h$, $x_1 = a+h$. Then

$$w(a) = -h^2, \quad w'(a) = 0$$
$$f'(a) \approx f[x_0, x_1] = \frac{f(a+h) - f(a-h)}{2h}$$
$$\text{error} = f[a-h, a+h, a, a](-h^2) = -\frac{h^2 f^{(3)}(c)}{6}$$

I recall $f'(x)$ is the divided difference based on x_0, x_1 plus the term containing divided difference based on x_0, x_1, x, x into $w(x)$ plus divided difference based on x_0, x_1, x and $w'(x)$. $w(x)$ is product of $x - x_0$ and $x - x_1$; the derivative of $w(x)$ is $x - x_0 + x - x_1$.

If we choose x to be equal to a , x_0 to be equal to $a - h$, x_1 to be equal to $a + h$, then $w(a)$ will not be 0; it will be equal to $-h^2$. But now $w'(a)$ is equal to 0, that gives us $f'(a)$ to be approximately equal to $f[x_0, x_1]$, that is $f(a+h) - f(a-h)$ divided by $2h$ and in the error, $w'(a)$ is 0. So, this term will not be there; so you will have only this term, which gives us $f(a-h)$ plus $f(a+h)$ multiplied by $w'(a)$ which is $-h^2$. So, you have $-h^2 f^{(3)}(c)$ divided by 6.

forward difference formula.

$$f'(a) \approx \frac{f(a+h) - f(a)}{h}$$
$$\lim_{h \rightarrow 0} \frac{f(a+h) - f(a)}{h} = f'(a).$$

NPTEL

Now, when one looks at these formulae which we obtained, they are something expected, like look at the forward difference formula, we had $f'(a)$ to be approximately equal to $f(a+h) - f(a)$ divided by h . Now, it is expected that, from the definition limit of $f(a+h) - f(a)$ divided by h , as h tends to 0 is equal to $f'(a)$.

So, maybe I do not have to do all these interpolating polynomials and then obtain this formula; this formula is available from the definition similarly, the other formula.

(Refer Slide Time: 32:08)

forward difference formula.

$$f'(a) \approx \frac{f(a+h) - f(a)}{h}$$
$$\lim_{h \rightarrow 0} \frac{f(a+h) - f(a)}{h} = f'(a).$$
$$\frac{f(a+h) - f(a-h)}{2h} \rightarrow f'(a)$$
$$\left(\frac{f(a+h) - f(a)}{h} + \frac{f(a) - f(a-h)}{h} \right) / 2.$$

The whiteboard also features an NPTEL logo in the bottom left corner.

The other formula was $f(a+h) - f(a-h)$ divided by $2h$. So, now, this I can write as $f(a+h)$ minus $f(a)$ divided by h plus $f(a)$ minus $f(a-h)$ divided by h and then, whole thing divided by 2. So, this will tend to $f'(a)$; this will tend to $f'(a)$ and hence, this will tend to $f'(a)$, because you are dividing by 2. So, both these formulae, central difference formula and forward difference formula, we could have written from the definition.

The reason I went through this interpolating polynomial is that gives us a general method. **that** Now, the same idea we are going to use for calculating the second derivative and we had idea about the discretization error, like no doubt these quotients or these approximations, they approximate to $f'(a)$. So, for h small enough, you are going to get an approximation, but we could tell that central difference formula in which case the interpolation points are symmetrically placed that formula is to be preferred, because the discretization error in that case is h^2 as compare to the discretization error h in case of forward difference formula. So, now, let us look **at the approximation** an approximation of second derivative.

Now, you are going to fit; if you fit a polynomial of degree less than or equal to 1 and take its second derivative, then the second derivative is going to be 0 and it is a crude approximation to our $f''(a)$. So, instead of a polynomial of degree less than or equal to 1, we should at least look at polynomial of degree less than or equal to 2. So, we

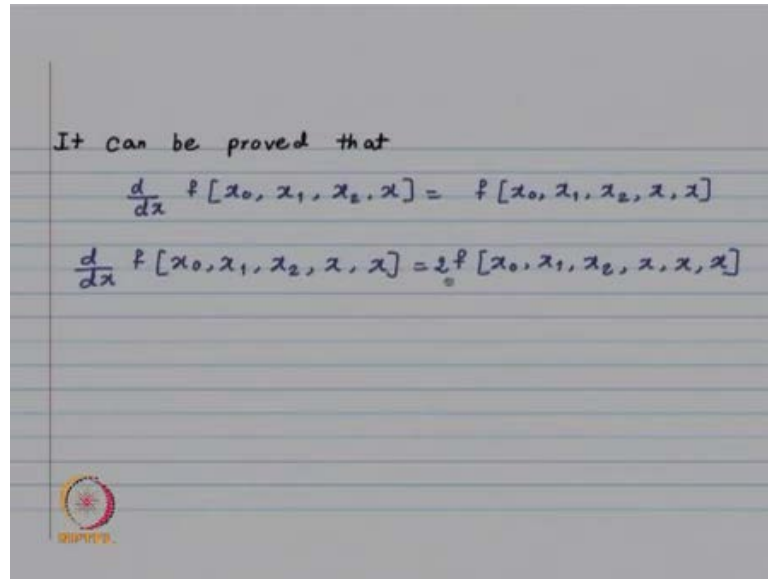

will consider three distinct points x_0, x_1, x_2 fit a parabola, take its second derivative and that will approximate $f''(a)$. In this case again, the points x_0, x_1, x_2 which we are going to choose, we will choose them in the vicinity. So, one choice can be x_0 is equal to a ; x_1 is equal to $a + h$; x_2 is equal to $a + 2h$.

So, that will give us forward difference formula; the other will be you place them symmetrically. Now, in this case, you can choose your points to be $x_0 = a - h$; $x_1 = a$, and $x_2 = a + h$. So, that will give you central difference formula. Now, here when we try to look at the error, the error is going to have a divided difference term which is based on x_0, x_1, x_2, x .

Now, we are going to take two derivatives. So, the first derivative the proof is similar what we have proved is, $f'(x)$ is the divided difference, its derivative is nothing but divided difference based on x_0, x_1, x . If you consider the divided difference $f'(x)$ based on x_0, x_1, x , its derivative is divided difference based on x_0, x_1, x, x , you have to just add $1/x$; similarly, divided difference of f' based on $x_0, x_1, x, x_0, x_1, x_2, x$ its derivative will be obtained by adding one more extra.

Now, we are going to take the second derivative. So, we will need to take the derivative of divided difference based on x_0, x_1, x_2, x repeated twice, its derivative will be the divided difference x_0, x_1, x_2, x repeated thrice. The proof is similar and what we are going to do is, we will do it as a tutorial problem.

(Refer Slide Time: 37:25)

It can be proved that

$$\frac{d}{dx} f[x_0, x_1, x_2, x] = f[x_0, x_1, x_2, x, x]$$
$$\frac{d}{dx} f[x_0, x_1, x_2, x, x] = 2 f[x_0, x_1, x_2, x, x, x]$$

So, at present assume that the derivative of $f[x_0, x_1, x_2, x]$ it will be divided difference based on x_0, x_1, x_2, x, x . And **its** the derivative of this divided difference based on x_0, x_1, x_2, x, x that will be two times divided difference based on x_0, x_1, x_2, x repeated thrice. So, this derivative, it is not only just add one x **x** extra, but there is also term two coming into picture.

(Refer Slide Time: 38:09)

Second derivatives

x_0, x_1, x_2 : distinct points in $[a, b]$

$$f(x) = f(x_0) + f[x_0, x_1](x-x_0) + f[x_0, x_1, x_2](x-x_0)(x-x_1) + f[x_0, x_1, x_2, x](x-x_0)(x-x_1)(x-x_2)$$

$\leftarrow p_2(x)$

$\underbrace{(x-x_0)(x-x_1)(x-x_2)}_{\omega(x)}$

$$f'(x) = p_2'(x) + f[x_0, x_1, x_2, x]\omega(x) + f[x_0, x_1, x_2, x]\omega'(x)$$

$$f''(x) = p_2''(x) + 2f[x_0, x_1, x_2, x, x]\omega(x) + f[x_0, x_1, x_2, x]\omega'(x) + f[x_0, x_1, x_2, x]\omega''(x)$$

Now, we are choosing three distinct points and the interval a, b should be interval c, d , then this is a quadratic polynomial, **in the** which is written using divided differences. This part is the error, take the first derivative. So, $f'(x)$ will be equal to $p_2'(x)$ plus we need to take the derivative of this; use the product rule; so first the derivative of this term. So, it is going to be $x_0, x_1, x_2, x, x \omega(x)$ plus this term as it is multiplied by $\omega'(x)$; so that is our first derivative. The second derivative will be $f''(x)$ is equal to $p_2''(x)$ plus derivative of this is going to be 2 times divided difference based on x_0, x_1, x_2, x repeated thrice multiplied by $\omega(x)$ as it is, then this multiplied by $\omega'(x)$, derivative of this multiplied by $\omega'(x)$. So, that together gives us two times divided difference based on x_0, x_1, x_2, x, x into $\omega'(x)$ and lastly, this divided difference multiplied by $\omega''(x)$.

(Refer Slide Time: 39:58)

$$\begin{aligned}
 f''(x) &= p_2''(x) + 2f[x_0, x_1, x_2, x, x, x] \omega(x) \\
 &+ 2f[x_0, x_1, x_2, x, x] \omega'(x) + f[x_0, x_1, x_2, x] \omega''(x) \\
 \omega(x) &= (x-x_0)(x-x_1)(x-x_2), \\
 \omega'(x) &= (x-x_0)(x-x_1) + (x-x_0)(x-x_2) + (x-x_1)(x-x_2) \\
 \omega''(x) &= 2\{(x-x_0) + (x-x_1) + (x-x_2)\} \\
 x = x_0 = a &\Rightarrow \omega(a) = 0, \\
 x_1 = a+h, \quad x_2 = a+2h &\Rightarrow \omega'(a) = -2h^2, \quad \omega''(a) = -6h \\
 x_1 = a-h, \quad x_2 = a+h &\Rightarrow \omega'(a) = -h^2, \quad \omega''(a) = 0
 \end{aligned}$$

So, $f''(x)$ is approximately equal to $p_2''(x)$ and this is going to be the error term. $\omega'(x)$ will be given by three terms $(x-x_0)(x-x_1) + (x-x_0)(x-x_2) + (x-x_1)(x-x_2)$. And the second derivative is given by this formula, if I choose x_0 to be equal to a , then $\omega(a)$ is going to be 0. Now, if I choose x_1 is equal to $a+h$; x_2 is equal to $a+2h$, then $\omega'(a)$ will be $-2h^2$ and $\omega''(a)$ will be $-6h$. If the x_1 and x_2 are chosen symmetrically, then $\omega(a)$ is already 0; $\omega'(a)$ will be equal to $-h^2$ and $\omega''(a)$ is going to be equal to 0. Because $\omega''(x)$ is given by this formula $(x-x_0)$ is already 0; $(x-x_1)$ will be $-h$; $(x-x_2)$ will be $+h$. So, that is why $\omega''(a)$ is 0; this choice is going to give us forward difference formula and this is going to give us central difference formula.

(Refer Slide Time: 41:23)

The image shows handwritten mathematical derivations on a lined background. The first part shows the second derivative approximation using three points: $f''(a) \approx \frac{2}{h^2} [f(a-h) - 2f(a) + f(a+h)]$. The error term is derived as $\text{error} = \frac{f^{(4)}(c)}{12} h^2 - \frac{f^{(3)}(d)}{6} h$. The second part shows the second derivative approximation using two points: $f''(a) \approx \frac{2}{h^2} [f(a) - 2f(a+h) + f(a+2h)]$. The error term is derived as $\text{error} = \frac{f^{(4)}(c)}{6} h^2 - \frac{f^{(3)}(d)}{2} h$. A small logo is visible in the bottom left corner of the slide.

So, in the first case when we are choosing our points to be $a - h$, a , $a + h$, $f''(a)$ is approximately equal to $\frac{f(a-h) - 2f(a) + f(a+h)}{h^2}$; the 2 gets cancelled with the 2 in the denominator for the divided difference. And now for the error term, we have only w at a is equal to 0.

So, we have this divided difference multiplied by $2h^2$ plus this divided difference multiplied by minus $6h$. So, you have $\frac{f^{(4)}(c)}{6} h^2 - \frac{f^{(3)}(d)}{2} h$ and if you have chosen them to be symmetrically, then we had w at a to be 0; $w''(a)$ to be 0. So, there is only one term and then, you have got $\frac{f^{(4)}(c)}{12} h^2$ as the discretization error.

So, when we look at the discretization error, if the points are $a - h$, a , $a + h$, then the discretization error is less than or equal to constant times h^2 , because we have got two terms; one term contains h^2 ; one term contains h , but then the term which contains h , that is going to decide the rate. So, you have got this to be less than or equal to constant times h . If your points are symmetric, then the discretization error is less than or equal to constant times h^2 .

So, we have got formulae for the first derivative, for the second derivative. This when we have fitted a polynomial of degree less than or equal to 2, that it can give us a formula for $f'(a)$ also, but what I wanted to do was illustrate, that using interpolation points we can obtain approximations to first derivative second derivative and so on.

And as I mentioned before, these approximations are going to be important in the numerical solution of differential equation. Now, look at our problem $f'(a)$, I want to find $f'(a)$. So, our approximation is either $\frac{f(a+h) - f(a)}{h}$ or $\frac{f(a+h) - f(a-h)}{2h}$, both these quotients, they converge to $f'(a)$, as h tends to 0. So, what I have to do is, choose my h to be small enough in order to have desired accuracy, because we have convergence; both these divided differences they tend to $f'(a)$ as h tends to 0. So, choose h small enough, then you will get the desired accuracy.

Now, when you try to do it in practice, you face certain difficulty, now what are the difficulties? You look at your $\frac{f(a+h) - f(a-h)}{2h}$. You are going to make h small. So, when your h is small enough, $f(a+h)$ and $f(a-h)$, they are going to be about equal; they are going to be near each other. So, you are going to subtract two numbers, which are approximately equal.

Now, as we have noticed that, **when you divide**- when you subtract two numbers using computer, if the two numbers are approximately the same, then there is loss of accuracy or there is loss of significant digits and then you are going to divide by h ; so you are dividing by a small number. So, these two facts they combine to make our divided difference approximation not as good as we will like it to be. So, here, for the divided difference approximation of $f'(a)$, the two difficulties are, you are **dividing** going to divide by a small number and you are going to subtract two numbers which are approximately the same.

(Refer Slide Time: 46:53)

Recall $f'(a) = \frac{f(a+h) - f(a-h)}{2h} - \frac{h^2}{6} f'''(c)$
↑
discretization

In calculations, we use
 $f(a+h) + E_1$ and $f(a-h) + E_2$, E_1, E_2 : round-off errors.

$$f'_{\text{comp}} = \frac{f(a+h) + E_1 - (f(a-h) + E_2)}{2h}$$
$$= \frac{f(a+h) - f(a-h)}{2h} + \frac{E_1 - E_2}{2h}$$
$$f'(a) = f'_{\text{comp}} - \frac{E_1 - E_2}{2h} - \frac{h^2}{6} f'''(c)$$

does not decrease

So, we have got $f'(a)$ is equal to $\frac{f(a+h) - f(a-h)}{2h}$ and this was the discretization error. In calculations, we instead of $f(a+h)$, we will have $f(a+h) + E_1$, and $f(a-h) + E_2$, where E_1 and E_2 are round off errors. So, instead of computing this quotient, what you will be computing will be, $\frac{f(a+h) + E_1 - (f(a-h) + E_2)}{2h}$. So, this is nothing but $\frac{f(a+h) - f(a-h)}{2h} + \frac{E_1 - E_2}{2h}$.

Substituting here, you have $f'(a)$ is equal to $f'_{\text{comp}} - \frac{E_1 - E_2}{2h} - \frac{h^2}{6} f'''(c)$. Now, E_1 and E_2 are round off errors; there is no reasons why they should cancel, they will increase and you are dividing by a small number. So, this term does not decrease; this is going to tend to 0. So, this is the difficulty one faces. So, when you reduce h up to a certain stage, you will get better and better approximation, but after a certain stage even if you reduce your h , instead of getting a better approximation, you will get worse approximation.

So, in the next lecture, I will once again compare these phenomena with the phenomena in the composite numerical integration and then, we will be considering solution of linear equations. So, thank you.
