Predictor-Corrector Formulae

Last time we derived Adams-Bashforth method. Today we are going to consider the local discretization error in this method. Then we are going to consider new class of methods which are known as predictor-corrector methods.

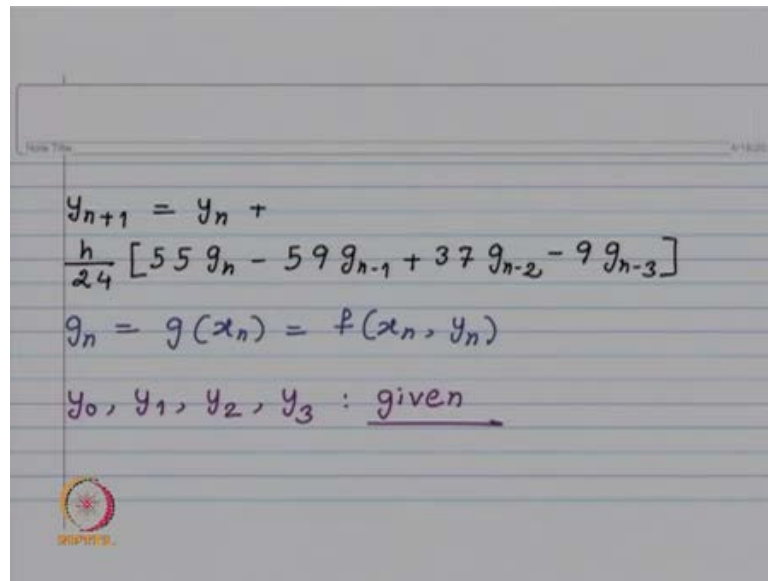

So, we will see what are the advantages in this new method, after that I am going to derive what is known as midpoint method and compare it with Euler's method and the stability consideration of the midpoint method.

So, Adams-Bashforth method we derived by using numerical quadrature. So, our right-hand side function is $f(x)$. So, that is the function of x for this function we fitted a cubic polynomial. So, we are integrating over the interval x_n to x_{n+1} .

The cubic polynomial which we fit that is going to interpolate our given function g at x_n , x_{n-1} , x_{n-2} , x_{n-3} . So, out of the four interpolation points only one belongs to the interval over which we are integrating and that gives us a formula. So, that is Adams-Bashforth formula.

Now, we know how to derive the error in the numerical quadrature. So, using that we will show that the local discretization error is of the order of h^5 . So, that is our Adams-Bashforth method.

(Refer Slide Time: 02:11)

The image shows a slide with handwritten mathematical formulas. The formulas are:

$$y_{n+1} = y_n + \frac{h}{24} [55g_n - 59g_{n-1} + 37g_{n-2} - 9g_{n-3}]$$
$$g_n = g(x_n) = f(x_n, y_n)$$
$$y_0, y_1, y_2, y_3 : \underline{\text{given}}$$

There is a small logo in the bottom left corner of the slide.

So, this is our initial value problem. $y' = f(x, y)$ with $y(a) = y_0$, that is given. We look at uniform partition of interval a, b . So, we divide it into n equal parts.

h is length of the subinterval $b - a$ by n . p_3 is the polynomial of degree less than or equal to 3, interpolating our function g at $x_n, x_{n-1}, x_{n-2}, x_{n-3}$. This is the exact equation.

So, y is our unknown solution $y_{n+1} - y_n = \int_{x_n}^{x_{n+1}} g(x) dx$. Then this g we are going to replace by our cubic polynomial interpolation.

So, here it should be $y_{n+1} = y_n + \int_{x_n}^{x_{n+1}} p_3(x) dx$, now this formula we derived yesterday.

So, we have got $y_{n+1} = y_n + \frac{h}{24} [55g_n - 59g_{n-1} + 37g_{n-2} - 9g_{n-3}]$, and the values which come into picture are $g_n, g_{n-1}, g_{n-2}, g_{n-3}$, where g_n is nothing, but $f(x_n, y_n)$. g_{n-1} will be $f(x_{n-1}, y_{n-1})$ and so on.

So, thus we have got a formula for y_{n+1} , in terms of y_n, y_{n-1}, y_{n-2} and y_{n-3} .

So, thus we need to be given y_0 , y_1 , y_2 and y_3 , in case of the single step formulae such as the Euler's method or Runge-Kutta methods y_0 is our initial condition. So, once you know y_0 you calculate y_1 you calculate y_2 and so on.

On the other hand in this method we need to know y_0 , y_1 , y_2 and y_3 . Once we know that then our procedure can continue then you calculate y_4 . Now for the y_4 you once you calculate y_4 , then y_5 will be in terms of y_1 , y_2 , y_3 , y_4 and so on.

So, these formulae are not self-starting. So, y_0 is given to us y_1 , y_2 , y_3 we need to calculate by some other method. Now we are going to show that local discretization error in the Adams-Bashforth formula is of the order of h^5 .

So, then y_1 , y_2 , y_3 also should be found with the same local discretization error h^5 , because if these are calculated less accurately then overall order of convergence is going to suffer.

So, then in the case of Runge-Kutta method of order 4, we have the local discretization error to be h^5 . So, using this formula calculate y_1 , y_2 , y_3 and now use this formula. Now why cannot I just continue with the Runge-Kutta method? The reason is here our y_{n+1} , we have seen that the formula is in terms of, y_n , y_{n-1} , y_{n-2} , y_{n-3} .

Then when you go to y_{n+2} then it will have y_{n+1} , y_n , y_{n-1} , y_{n-2} let me write

(Refer Slide Time:06:26)

$$y_{n+1} : \underbrace{y_n, y_{n-1}, y_{n-2}, y_{n-3}}$$
$$y_{n+2} : \underbrace{y_{n+1}, y_n, y_{n-1}, y_{n-2}}$$

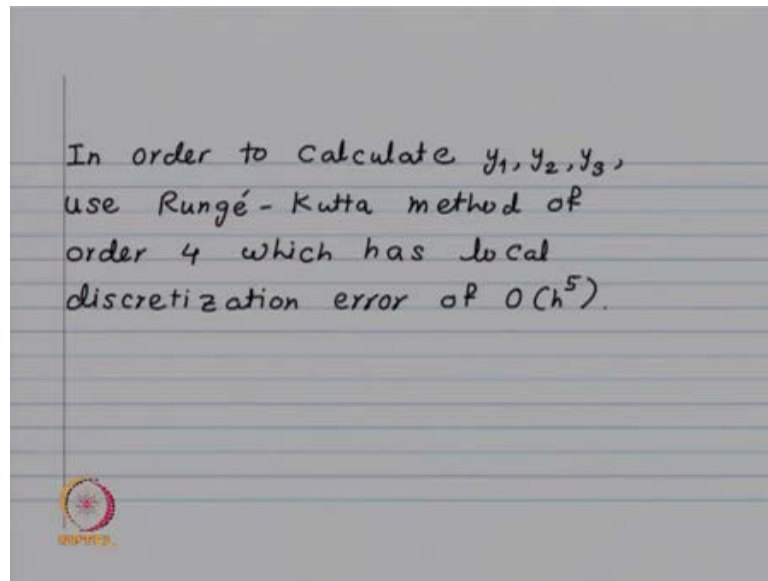

So, in order to calculate y_{n+1} what comes into picture is $y_n, y_{n-1}, y_{n-2}, y_{n-3}$. When you look at y_{n+2} ,

It will be $y_{n+1}, y_n, y_{n-1}, y_{n-2}$. So, these three values. They are common to both y_{n+1} and y_{n+2} . So, thus in the case of Adams-Bashforth method except for the first step, afterwards you are going to have only one function evaluation per step.

In case of Runge-Kutta method of order 4, you have four function evaluations per step. So, that four you are reducing it to one, while retaining the local discretization error to be h^5 . So, that is the advantage of Adams-Bashforth method as compared to the Runge-Kutta method of order 4.

So, now let us look at the error in the Adams-Bashforth formula.

(Refer Slide Time; 07:46)

So, we have the this is the error term integral x_n to x_{n+1} divided difference of g based on $x_n, x_{n-1}, x_{n-2}, x_{n-3}$.

These where the interpolation points x multiplied by $x - x_n, x - x_{n-1}, x - x_{n-2}, x - x_{n-3}$ dx . Now you know that you can assuming g to be sufficiently differentiable, then one can show that this is equal to also look at this.

Your integration is over x_n to x_{n+1} . So, when I look at $x - x_n, x - x_{n-1}, x - x_{n-2}, x - x_{n-3}$. This function is going to be bigger than or equal to 0.

So, you can use mean value theorem for integral. Using the mean value theorem, for integrals the divided difference, will come out as the divided difference evaluated at some point c this is a polynomial. So, you can integrate and then when does the calculations it comes out to be $\frac{1}{720} h^5$ 4th derivative of g at some point d a our y'''' is equal to f which is equal to g .

So, that is why g four is going to be y five. So, this is going to be the error in the Adams-Bashforth formula and it is of the order of h^5 and in order to calculate y_1, y_2, y_3 use Runge-Kutta method of order 4 which has local discretization error of the order of h^5 .

So, now we are going to consider predictor corrector formulae. We started with numerical integration, then when you use rectangle rule, then what you get is Euler's method after the rectangle rule suppose I want to consider the trapezoidal rule.

Then on the left hand side I will have y_{n+1} on the right hand side, also there will be y_{n+1} . So, y_{n+1} will be defined only implicitly that is why even in the Adams-Bashforth method, we did not include x_{n+1} as an interpolation point, but we took the earlier interpolation point. So, we are going to look at trapezoidal rule.

And then we will apply iteration method and that gives rise to what are known as predictor corrector formulae.

(Refer Slide Time : 10:51)

Fix x_n Define

$$y_{n+1}^{(0)} = y_n + h f(x_n, y_n)$$

$$y_{n+1}^{(1)} = y_n + h \frac{[f(x_n, y_n) + f(x_{n+1}, y_{n+1}^{(0)})]}{2},$$

$$y_{n+1}^{(k)} = y_n + h \frac{[f(x_n, y_n) + f(x_{n+1}, y_{n+1}^{(k-1)})]}{2}$$

So, we have this, is the exact equation the trapezoidal rule will be the right hand side will be approximated by h by 2 h is the length of the interval x_{n+1} minus x_n .

So, h by 2 f of x_n y_n plus f of x_{n+1} y_{n+1} . So, you have got y_{n+1} here you have got y_{n+1} . Here the function f it may be something we are not saying that f should be some simple function, or f is any general function. So, that is why you have got only implicit definition of y_{n+1} when we look at the Euler's method you had y_{n+1} is equal to y_n plus h times f of x_n y_n .

So, you have a formula now here is only implicit and then the error, this is the error in the trapezoidal rule. So, that is minus h^3 by twelve $y'''(x_n)$. So, the idea is look at the Euler's method.

Here the error is of the order of h^2 this is your trapezoidal rule, here y_{n+1} is defined only implicitly. So, calculate y_{n+1} using this Euler's method. So, let us call it $y_{n+1}^{(0)}$.

Substitute in this formula and then you will get $y_{n+1}^{(1)}$, then whatever value you get you substitute again. So, you are going to calculate y_{n+1} iteratively. So, here the formula which is given by Euler's method that is known as predictor formula or the open formula.

The formula which is given by trapezoidal rule, that is known as corrector formula. In general the corrector formula is more accurate than the predictor, here you have local discretization error to be h^3 here you have got h^2 . So, we are going to define the iterations scheme and that is known as predictor corrector formula.

So, let me describe that. So, we have fix x_n this is i am using the Euler's formula then $y_{n+1}^{(1)}$ is equal to y_n plus $h f(x_n, y_n)$. So, this is the trapezoidal rule.

So, i substitute here $y_{n+1}^{(0)}$ in general $y_{n+1}^{(k)}$ is equal to y_n plus h times f of x_n, y_n plus f of $x_{n+1}^{(k-1)}, y_{n+1}^{(k-1)}$ divided by 2. So, **So**, now, we are doing iteration.

So, we have to tell. So, in this algorithm what one needs to tell is what is your h the length of the subinterval, then how many iterates I should have some stopping criteria.

For this iteration scheme. So, suppose I said that the maximum number should be capital k now at each stage, what one will do is check the relative error in the successive iterates.

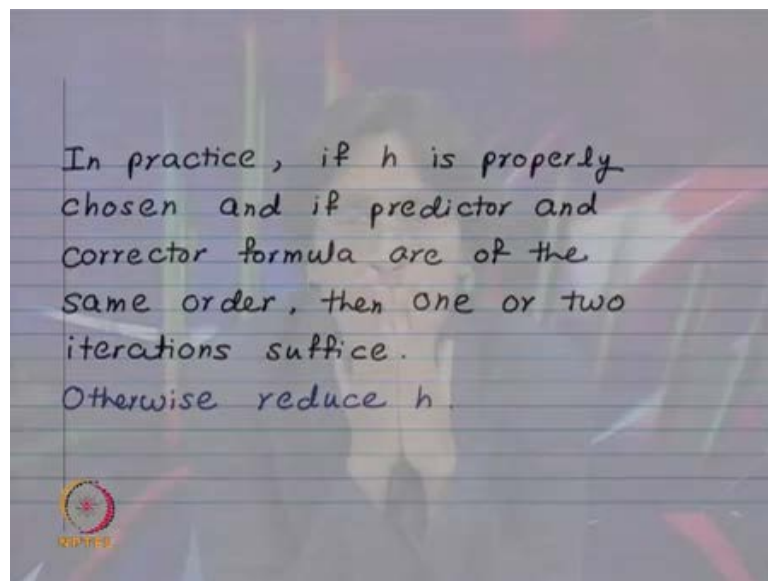

If that relative error is less than a prescribed epsilon, then you stop otherwise you give some maximum number of iterate. If even after doing the maximum number of iterates if your relative error is not less than epsilon, then what one can do is replace h by $h/2$.

Reduce your step size in practice, if you have chosen the step size correctly then you need to evaluate only 1 or 2 iterates. So, you calculate 1 or 2 iterates and then you are

going to get formula. Now the advantage is our predictor formula has local discretization error only h^2 whereas, our corrector formula has local discretization error h^3 . So, we are trying to obtain a better approximation.

Of course it increases your work because you will be calculating the iterates 1 or 2 iterates. So, that will involve the function evaluation, but then you are getting a better solution

(Refer Slide Time : 15:57)

So, we have ϵ is prescribed stop the iteration when the relative error. So, these are our successive iterates then you divide by modulus of y_{n+1}^k . So, that it becomes a relative error this should be less than ϵ .

So, that tells us how many iterates we should calculate. So, as I said euler's formula is open or predictor formula trapezoidal rule is closed or corrector formula and generally corrector formula is more accurate than predictor formula, and this for the algorithms we need to specify h maximum number of iterations and what to do if k exceeds capital k .

So, in general you will need only one or two iterations, otherwise you reduce h and then you continue. So, we have considered one predictor corrector formula now we can use this idea and define other corrector predictor corrector formula.

So, when we derived adams bashforth method, we had considered cubic interpolation polynomial which interpolates our function g at $x_n, x_{n-1}, x_{n-2}, x_{n-3}$.

If instead of choosing these interpolation points if I chose the interpolation points to be $x_{n+1}, x_n, x_{n-1}, x_{n-2}$, then I will get a formula that formula will define y_{n+1} implicitly.

Like in case of the trapezoidal rule then use Adams-Bashforth method as your predictor formula. So, we had considered pair of formulae it was Euler's method and trapezoidal rule.

Now, instead of that instead of Euler's method we are going to consider Adams-Bashforth method and the corrector formula is going to be the one, which is obtained by replacing function g by a cubic polynomial interpolation with interpolation points as $x_{n+1}, x_n, x_{n-1}, x_{n-2}$. Now here the order of convergence or the error is going to be h^5 in both the methods.

For Euler's method we had h^2 trapezoidal it was h^3 , but now the formula which I am going to define it will have both to be h^5 , but in the corrector formula the coefficient is going to be smaller.

And advantage in this method is going to be we will have some idea about the error like what we are doing in this methods is y is our unknown solution. So, we try to approximate value of y at points x_n and then our approximations are we are denoting by y_n .

So, when I consider the error y at x_n minus y_n I know that their local discretization error in various methods I know, but I have no idea how much the error is going to be. So, in this method which we are going to define now we will have an idea about the exact error how much it is going to be.

(Refer Slide Time: 20:02)

The image shows handwritten mathematical equations on a lined background. The equations are:

$$E_{AB} = \frac{251}{720} y^{(5)}(c_n) h^5$$

$$E_{AM} = -\frac{19}{720} y^{(5)}(d_n) h^5$$

$$y(x_{n+1}) - y_{n+1}^{(0)} = \frac{251}{720} y^{(5)}(c_n) h^5$$

$$y(x_{n+1}) - y_{n+1}^{(1)} = -\frac{19}{720} y^{(5)}(d_n) h^5$$

$$y_{n+1}^{(1)} - y_{n+1}^{(0)} \approx \frac{270}{720} y^{(5)}(d_n) h^5$$

There is a small circular logo in the bottom left corner of the slide.

So, let us look at this method this method is known as Adams Moulton method. This is the equation satisfied by the exact solution y_p is the polynomial of degree less than or equal to three interpolating the given function at x_{n+1} , x_n , x_{n-1} , x_{n-2} .

So, now the interpolation points are x_{n+1} and x_n . These are going to be in the our interval over which we are integrating, and these are to the exterior in case of Adams Bashforth only x_n was in the interval of integration.

Whereas x_{n-1} , x_{n-2} , x_{n-3} they were outside the interval of integration then $y_{n+1} - y_n$ is integral x_n to x_{n+1} of $p_3(x) dx$, I skip the details. So, you are going to get a formula of this type h by 24 and then on the you have g_{n+1} , g_n , g_{n-1} , g_{n-2} , g_n is g at x_n which is nothing, but f of x_n , y_n .

So, here you have got y_{n+1} in g_{n+1} you will have f of x_{n+1} , y_{n+1} . So, once again the y_{n+1} is going to be defined implicitly you have here as well as here and the error as I said that it is of the order of h^5 , but the coefficient now is smaller than in case of Adams Bashforth method.

So, the error is $-\frac{19}{720} h^5 y^{(5)}$ and then some point d this is the Adams Moulton predictor corrector method.

y_0, y_1, y_2, y_3 they are given calculate y_{n+10} using adams bashforth formula. So, what we had used earlier euler's formula, now we are using adams bashforth formula once you calculate y_{n+10} then you use adams-moulton formula.

So, y_{n+k} will be equal to $y_n + h \sum_{j=0}^{k-1} f(x_{n+j}, y_{n+j})$.

So, here you have k **here you have k** minus 1 g_n, g_{n-1}, g_{n-2} , that will involve $f(x_n, y_n), f(x_{n-1}, y_{n-1}), f(x_{n-2}, y_{n-2})$ which you have already calculated.

And then iterate on k until the relative error it becomes less than epsilon. So, starting iterate y_{n+10} is obtain by using adams bashforth method then use adams-moulton formula for calculating y_{n+k} and iterate till the relative error is less than a prescribed epsilon.

So, here you have got error in the adams bashforth method it is h^5 , but the coefficient $251/720$ this is the error in adams-moulton method. So, here you have got $19/720 y^{(5)}(c_n) h^5$. So, this y_{n+10} it was obtained by using adams bashforth formula. So, when I look at the error.

y_{n+10} this will be $251/720 y^{(5)}$ evaluated at c_n h^5 , the first iterate when you calculate it involves adams-moulton method. So, you have got $y_{n+1} - y_{n+1}$ to be $19/720 y^{(5)}(d_n) h^5$.

Now, in general your c_n and d_n they are going to be different, but let us assume that our interval is small the interval x_n to x_{n+1} is small and the fifth derivative of y it does not change too much.

So, if that is the case then I can assume that $y^{(5)}$ the fifth derivative of y whether I evaluate at c_n or whether I evaluated d_n they are going to be about the

(Refer Slide Time: 25:21)

$$y(x_{n+1}) - y_{n+1}^{(1)} = -\frac{19}{720} y^{(5)}(d_n) h^5$$

$$y_{n+1}^{(1)} - y_{n+1}^{(0)} \approx \frac{270}{720} y^{(5)}(d_n) h^5$$

$$y(x_{n+1}) - y_{n+1}^{(1)} \approx -\frac{19}{270} (y_{n+1}^{(1)} - y_{n+1}^{(0)})$$

$$\approx -\frac{1}{14} (y_{n+1}^{(1)} - y_{n+1}^{(0)})$$

$$= D_{n+1}$$

then using that fact you will have. So, suppose this $y^{(5)}(d_n)$ and $y^{(5)}(d_n)$ they are about the same.

Now, let me subtract these 2 equations. So, $y(x_{n+1})$ will get cancelled and I will have $y_{n+1}^{(1)} - y_{n+1}^{(0)}$ to be equal to $-\frac{19}{270} (y_{n+1}^{(1)} - y_{n+1}^{(0)})$. So, it is 270 by 720 $y^{(5)}(d_n) h^5$.

So, what we are going to do is this is the exact error in the exact error you have got fifth derivative of y evaluated at d_n we do not know what the fifth derivative is.

Now, for this $y^{(5)}(d_n) h^5$ I am going to substitute from here. So, $y^{(5)}(d_n) h^5$ will be 720 by 270 and then this what is the advantage this $y_{n+1}^{(1)}$, we have calculated.

$y_{n+1}^{(0)}$ we have calculated. So, this is something I know how to calculate. So, let me substitute for $y^{(5)}(d_n) h^5$ from this equation and then I will get. So, we have we have seen that $y_{n+1}^{(1)} - y_{n+1}^{(0)}$ is approximately equal to $\frac{270}{720} y^{(5)}(d_n) h^5$ substitute from here in this equation. So, you will get $-\frac{19}{270} (y_{n+1}^{(1)} - y_{n+1}^{(0)})$.

Which is $-\frac{1}{14}$ into this. So, thus the error in the first iterate in the Adams-Moulton predictor-corrector formula that is going to be approximately equal. To look at the error or the difference, between $y_{n+1}^{(1)}$ the iterate minus $y_{n+1}^{(0)}$.

So, we have gotten by using adams bashforth method we have calculated y_{n+1} take their difference. So, we know what that divide by fourteen. So, this whatever is that number that is going to be the error in the $y_{n+1} - y_{n+1}$. So, that is the error in the adams-moulton method. So, this is the advantage of adams-moulton method.

That it tells us you can calculate the exact error now if i can calculate the exact error then i can do step control like. So, far what we have been doing is start with interval a b subdivide it into equal parts.

Our h is $b - a$ by n now what we can do is at each stage we can look at the error. So, this error ,we **we** like we want our error to be less than some number say, i want it to be less than 10^{-6} ,and then also i will have some lower ,that i want it ten raise to minus 6, but i also want it to be say bigger than or 10^{-10} means, i will have some 2 bounds .Now if your errors at satisfies, these 2 bounds then you continue with the same age otherwise you change the step length.

So, see we have got say interval a b we are subdividing into n equal parts h is the step length now what one can do is throughout now replace h by **h by 2**, but then that increases your work.

So, what we want is a more flexible control over our step size h .

(Refer Slide Time: 30:04)

Comparison

RK method of order 4	AB	AM
$O(h^5)$	$O(h^5)$	$O(h^5)$
self-starting	x	x
4 function evaluation /step	1	2
		error control

So, d_{n+1} is going to be our $10^{-14} y_{n+1} - y_n + 10$. So, modulus of d_{n+1} by h that is going to be local error or units step suppose we want our local error per unit step 2 lie between e_1 and e_2 . If you for a particular n , if it is between e_1 and e_2 then you continue with the same step.

If it is say modulus of d_{n+1} by h is bigger than e_2 , then you should reduce h by 2 and if it is less than e_1 here increase h to $2h$. So, here as an example we can look at say 10^{-6} is less than modulus of d_{n+1} by h less than 10^{-4} . So, suppose this is these are my bounds.

So, if modulus of d_{n+1} by h if it is becoming bigger than 10^{-4} then we need to reduce h to $h/2$ if modulus of d_{n+1} by h is less than 10^{-6} then I am getting more accuracy. So, maybe I do not need this much of accuracy. So, then I will increase my h to $2h$. So, that is how we have a control over the step length h .

So, here is the comparison. So, we have got three methods Runge-Kutta method of order four Adams-Bashforth and Adams-Moulton in all the four methods the local discretization error is of the order of h^5 advantage of Runge-Kutta method, is that it is self starting.

Whereas Adams-Bashforth and Adams-Moulton they are not self starting we need to calculate y_1, y_2, y_3 by using some other method. When you compare the function evaluations Runge-Kutta method, it has got the maximum number of function evaluations and that is going to be four. In Adams-Bashforth method, you have got only function evaluation and in case of Adams-Moulton you will have two function evaluation let us assume that you are doing only one iterate.

So, you have got two function evaluations. So, when you compare Adams-Bashforth and Adams-Moulton for Adams-Moulton the number of function evaluation is twice as compare to Adams-Bashforth method, but then we have got the error control and also the coefficient in the error of Adams-Moulton method it is smaller as compare to Adams-Bashforth method. So, Adams-Moulton is going to give us better result.

So, as I said many times there is a trade off and the methods, which survive they have got some merit like if one particular method is better than some other method in all the

respect like here ,what we do is we consider the computational effort order of convergence and now we are going to look at what is known as stability.

So, if one particular method is better than the other method in all respects then the other method will not survive because as you know one can write several methods we have got a verity of methods.

You have got numerical quadrature. So, . So, now, the numerical quadrature is obtained by considering interpolating polynomials. So, your numerical quadrature depends on your choice of interpolation points what degree of polynomial you are taking. So, we can have we can write many methods, but what we are studying are the representative methods and which are better in some respect than other method.

So, runge kutta method is a single step method whereas, adams bashforth and adams-moulton method they are multi step methods.

All have local descritization error to be h^5 runge kutta method is a classical method where as adams bashforth and adoms-moulton method they are of relatively recent origin.

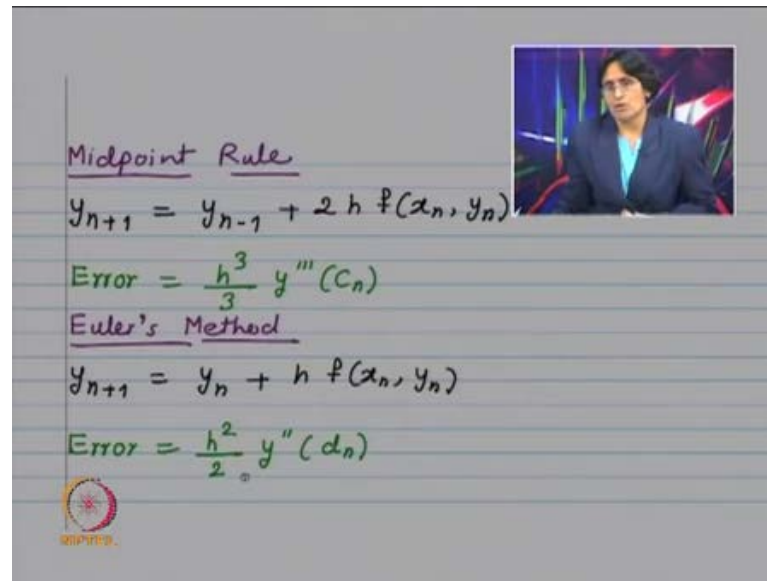

Now, what i want to do is i want to consider midpoint rule. So, we have we stared with rectangle rule the rectangle rule gives us euler's method then the trapezoidal method we considered in the predictor corrector formula now i want to look at midpoint method.

So, if i integrate over x_n to x_{n+1} and use midpoint formula ,that introduces a new node which i do not want.

So, what we are going to do is instead of integrating over x_n to x_{n+1} we will integrate,over x_{n-1} to x_{n+1} So, we have got our interval of length $2h$ if you consider interval x_{n-1} to x_{n+1} its midpoint is going to be equal to x_n .

So, you are not introducing a new node. So, let us look at what midpoint method looks like and let us see what are the merits of it.

(Refer Slide Time: 36:42)

Midpoint Rule
$$y_{n+1} = y_{n-1} + 2h f(x_n, y_n)$$
$$\text{Error} = \frac{h^3}{3} y'''(c_n)$$

Euler's Method
$$y_{n+1} = y_n + h f(x_n, y_n)$$
$$\text{Error} = \frac{h^2}{2} y''(d_n)$$

So, as usual this is our initial value problem this is the equation satisfied by the unknown solution y and now instead of taking integration]- integration over x_n to x_{n+1} we are taking over x_{n-1} to x_n plus 1.

So, you will have y_{n+1} is equal to y_{n-1} plus 2 h value of f at the midpoint. So, that is $g(x_n, y_n)$. So, it is $2h f(x_n, y_n)$. So, thus the midpoint rule is y_{n+1} is equal to y_{n-1} plus $2h f(x_n, y_n)$ Euler's method was y_{n+1} is equal to y_n plus h .

$f(x_n, y_n)$ the error in the midpoint rule is of the order of h^3 and the error in the Euler's method is of the order of h^2 . So, when we consider the midpoint rule and Euler's method they are very much similar in Euler's method, you add f of h times f of x_n, y_n in midpoint rule, you add $2h$ times f of x_n, y_n to y_{n-1} .

So, when you consider the complexity the number of function evaluation it is going to be exactly the same, but in the midpoint method you are obtaining the local discretization error to be h^3 whereas, in the Euler's method it is only h^2 . So, **So**, now, this method midpoint method should be even better than Runge-Kutta method of order 2, in the case of Runge-Kutta method of order 2 we had two function evaluation.

It was $y_{n+1} = y_n + h f(x_n, y_n)$ where k_1 was $h f(x_n, y_n)$ and k_2 was $h f(x_n + h, y_n + k_1)$.

So, we had 2 evaluation. So, . So, now, here you have got only one function evaluation local error is h^3 . So, . In fact, this method it should make the euler's method and runge kutta method redundant.

Because as i said that what we compare is the local descritization error and function evaluation. So, when you compare euler's method and the midpoint method ,the function evaluations is the same and the local descritization error is one degree more in the midpoint method.

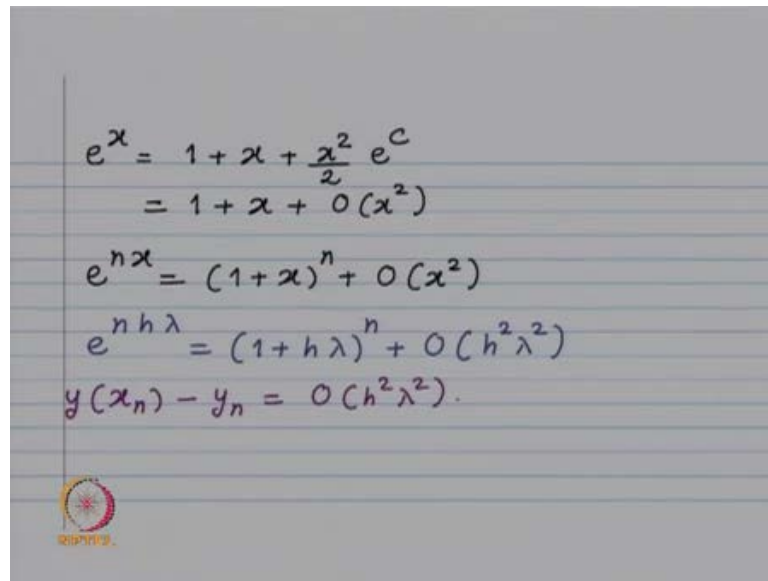

So, midpoint method is superior to euler's method, if you compare the midpoint method with runge kutta method both have the same descritization error of the order of h^3 , but the number of function evaluations is double in case of runge kutta method. So, then again the midpoint method is superior to runge kutta method, but still these two methods they have survived and that is because this midpoint method it has stability problems.

So, what the stability problems are that we are going to see now before we do that i just want to remark one more thing that in case of the midpoint method we have got y_{n+1} plus 1 is equal to y_n minus 1 plus $2h$ times f of x_n y_n .

That means this formula i cannot use for y_1 because for y_1 i will have to go to y_0 of minus 1 which we do not know.

. So, here you need to be given what is y_0 and what is y_1 y_0 comes with the problem y_1 you will have to find from some other formula. So, this midpoint method again it will not be a self starting method.

(ReferSlideTime: 41:16)

$$\begin{aligned}e^x &= 1 + x + \frac{x^2}{2} e^c \\ &= 1 + x + O(x^2) \\ e^{nx} &= (1+x)^n + O(x^2) \\ e^{nh\lambda} &= (1+h\lambda)^n + O(h^2 \lambda^2) \\ y(x_n) - y_n &= O(h^2 \lambda^2).\end{aligned}$$

Look at this example. So, this example it is from Conte-de Boor book here the exact solution is $y(x)$ is equal to $\frac{1}{2} e^{-2x}$ plus half here as given the result for interval 0 to 4

And h was chosen to be $\frac{1}{32}$ you can yourself do the computations. So, what we want to do is we want to compare the midpoint method and the Euler's method. So, here are some of the results. So, x_n 's I am giving the selected values 0, 0.5, 1, 1.5, 2, etcetera at 0 Euler and midpoint the error is 0.

Now, look at the error in Euler's method. So, it is 0.059, 0.427, 2.32, then 10 has increased and then 1 more 0 has increased.

So, the error in Euler's method it is monotonically decreasing on the other hand if you consider the midpoint method when you have zero point five here you have 142 and 0.000

So, for 0.5 the midpoint method gives you better results than at 1.0, still the midpoint method it is better for 1.5. Now it is becoming worse here, 2.0 it is worse and then still worse. So, compare to Euler's method.

In the midpoint method the error it is increasing whereas, in case of Euler's method we had a monotonically decreasing error. So, there is some problem with the midpoint method.

So, we have y' is equal to λy . Let us look at this initial value problem, y_0 is equal to 1. The exact solution of this differential equation is $y(x)$ is equal to $e^{\lambda x}$ belonging to say interval $[0, b]$.

If h is b/n then y_{n+1} will be equal to $y_n + h\lambda y_n$. So, you have got $1 + h\lambda$ into y_n and then use again the same relation to obtain y_{n+1} is equal to $(1 + h\lambda)^{n+1}$. So, we have got look at $e^{\lambda x}$ can be written as $1 + x\lambda + \frac{x^2\lambda^2}{2} + \dots$. So, the term $x^2\lambda^2/2$ can be written as term of the order of x^2 . So, $e^{\lambda x}$ will be $1 + x\lambda + \frac{x^2\lambda^2}{2} + \dots$ use binomial series expansion; that means, $(1 + h\lambda)^{n+1}$ is equal to $1 + (n+1)h\lambda + \frac{(n+1)n}{2}h^2\lambda^2 + \dots$ terms of the order of $h^2\lambda^2$.

So, we have the exact solution is $e^{\lambda x}$ and h is our x/n . So, you have $y(x) - y_n$ is equal to order of $h^2\lambda^2$.

So, as h tends to 0 the error is going to tend to 0. So, this is for the Euler's method now let us look at Runge-Kutta method. So, if I look at Runge-Kutta method of order 2.

(Refer Slide Time: 45:31)

Runge - Kutta Method of order 2

$$y' = \lambda y, \quad y(0) = 1,$$

$$y_{n+1} = y_n + \frac{k_1 + k_2}{2},$$

$$k_1 = h f(x_n, y_n) = h \lambda y_n$$

$$k_2 = h f(x_n + h, y_n + k_1) = h \lambda (1 + h\lambda) y_n$$

$$y_{n+1} = y_n + h \lambda y_n + \frac{h^2 \lambda^2}{2} y_n$$

$$= \left(1 + h\lambda + \frac{h^2 \lambda^2}{2}\right)^{n+1}.$$

in that case again we can calculate. So, y' is equal to λy y_0 is equal to 1 y_{n+1} is equal to $y_n + k_1 + k_2/2$ k_1 is h times f of x_n, y_n our $f(x, y)$ is λy . So, it is $h\lambda y_n$ k_2 is h f of $x_n + h, y_n + k_1$. So, this will be $h\lambda(1 + h\lambda)y_n$.

plus $h \lambda y_n$. So, that will give you y_{n+1} to be equal to $y_n + h \lambda y_n + \frac{h^2 \lambda^2}{2} y_n$. So, it is $1 + h \lambda + \frac{h^2 \lambda^2}{2}$ raised to n plus 1 so

In case of Euler's method we had e^x to be approximately equal to $1 + x$ now here you have got one more term. So, your e^x is approximately equal to $1 + x + \frac{x^2}{2}$.

So, for these two methods there will not be any problem as h tends to 0 you are going to have the error will decrease now next time what we are going to see is when you consider the midpoint method your differential equation is of order one it will be replaced by difference equation of order 2. So, that gives rise to extraneous solution and for some values of λ this extraneous solution or the super clear solution that is going to dominate the true solution and that creates the problem.

So, this is the stability. So, we will consider this in more detail in the next lecture and then we are going to consider the approximate solution of boundary value problems. So, thank you.
