**Lecture - 22**  
**Poisson Process**

So, till now we have discussed what the discrete time arrival process is. Now we are going to discuss the continuous time arrival process that is a Poisson process.

(Refer Slide Time: 00:12)

In this lecture, I am going to develop what is the Poisson process and how we can get the Poisson process from the scratch. Suppose you consider the process of arrival of customers at a barber shop. So this is the same example, we have discussed in the beginning of this course also. So over the time, how many arrivals is going to take place? That is going to be a random variable. So let  $N_t$ ,  $N$  suffix  $t$  or in some books they uses  $N(t)$ .

So the  $N(t)$  denotes number of arrivals occur during the interval zero to the closed interval zero to  $t$ . That means we are defining a random variable  $N(t)$  that denotes the number of arrival occurs during the interval zero to  $t$ . For fixed  $t$ ,  $N(t)$  is going to be a random variable. Therefore,  $N(t)$  over the time, because  $t$  is greater than or equal to zero, this is going to be a since the possible values of a capital  $T$  that is the parameter space is going to zero to infinity, therefore this is going to under the classification of a continuous parameter or continuous time.

And the possible values of  $N(t)$  for different values of  $t$  that is going to be takes the value zero or one or two, therefore it is going to be a countably infinite. Therefore, this is going to be a continuous time or continuous parameter discrete state stochastic process. So, this is the  $N(t)$  over the  $t$  greater than or equal to zero that is going to be a continuous time discrete state stochastic process. Now, we are going to develop the theory behind Poisson process.

To create the Poisson process, you need few assumptions so that you can able to develop the Poisson process. The first assumption, in a small negligible interval, if the interval is  $t$  to  $t + \Delta t$ , then the probability of one arrival is going to be  $\lambda \Delta t + O(\Delta t)$ . The probability of one arrival occurs during the interval  $t$  to  $t + \Delta t$  is going to be  $\lambda \Delta t + O(\Delta t)$ .

Here the  $\lambda$  is going to be strictly greater than zero and we are going to discuss what is  $\lambda$  and so on in the later, after explaining the Poisson process. So here the  $\lambda$  is going to be a constant and which takes the value greater than zero. And the  $O(\Delta t)$  means as  $\Delta t$  tends to zero the order of  $\Delta t$  that is going to be tends to zero, as  $\Delta t$  tends to zero. So this is the first assumption.

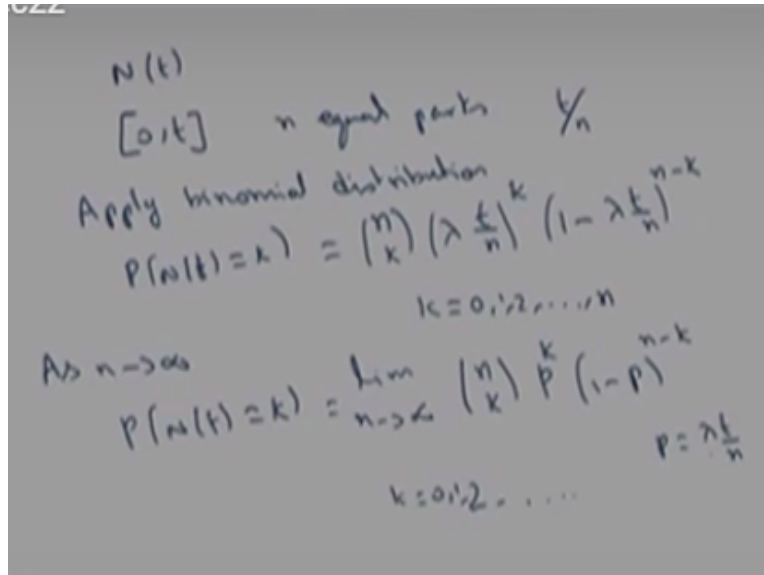

The second assumption, the probability of more than one arrival is going to be an order of  $\Delta t$ , in a same interval  $t$  to  $t + \Delta t$ , more than one arrival in this small negligible interval that probability is an order of  $\Delta t$ . That means, as  $\Delta t$  tends to zero, this values is going to tends to zero. Then the third assumption, occurrence of arrivals in a non-overlapping intervals are mutually independent. Non-overlapping intervals are independent. So this is very important assumption.

That means, what is the probability that the arrival occurs in a non-overlapping intervals that probability is same as the product of a probability of an arrival occurs in the each interval. Therefore, it is going to satisfy the independent property, occurrence of events in non-overlapping intervals are mutually independent. Therefore, the probability is going to be

probability of intersection of all those things is same as the probability of individual probability and their product.

So with these three assumptions, we are going to develop the Poisson process.

**(Refer Slide Time: 05:32)**

$N(t)$   
 $[0, t]$   $n$  equal parts  $\frac{t}{n}$   
 Apply binomial distribution  
 $P(N(t)=k) = \binom{n}{k} \left(\lambda \frac{t}{n}\right)^k \left(1 - \lambda \frac{t}{n}\right)^{n-k}$   
 $k=0,1,2,\dots,n$   
 As  $n \rightarrow \infty$   
 $P(N(t)=k) = \lim_{n \rightarrow \infty} \binom{n}{k} p^k (1-p)^{n-k}$   
 $k=0,1,2,\dots$   $p = \lambda \frac{t}{n}$

So what I am going to do, since I started with the random variable  $N(t)$  is the number of arrivals in the interval zero to  $t$ , I am going to partition the interval zero to  $t$  into  $n$  equal parts. I am going to partition the interval zero to  $t$  into  $n$  equal parts. Since I made it the interval zero to  $t$  into  $n$  equal parts, then each will be of the length  $t/n$ . And since I made the assumption the non-overlapping intervals are independent.

And the probability of one arrival is  $\lambda \Delta t$  and the probability of more than one arrival is order of  $\Delta t$  and so on, therefore I can apply binomial distribution. The way I have partitioned the interval zero to  $t$  into  $n$  pieces, therefore this is going to be a, of a  $n$  intervals of interval length  $t/n$ . Therefore, I can say what is the probability that I can able to find out, what is the probability that  $K$  arrivals takes place in the interval,  $n$  intervals of each length  $t/n$ .

What is the probability that  $K$  arrivals takes place, therefore the possible values of  $K$  is going to be zero to  $n$  and I can able to find out by using the binomial distribution, what is the probability that  $n$  of  $t$  takes the value  $K$ . Since non overlapping intervals are independent and each

probability of one arrival is  $\lambda \Delta t$ , where  $\Delta t$  is  $t/n$ . So each interval behaves as a Bernoulli trial, whether the arrival occurs or there is no arrival and like that you have  $n$  such independent trials.

Therefore, the sum of  $n$  independent Bernoulli trials land up a binomial trials. Therefore, by using the binomial distribution, I can able to get what is a probability that  $N(t)$  takes a value  $K$  that is what is the possible  $\binom{n}{k}$  way. And what is the probability of arrival takes place in one interval that is  $\lambda \Delta t$ , this interval length is  $t/n$ ,  $\lambda \Delta t$  power  $k$ . And what is the probability of no arrival takes place in each interval that is one minus  $\lambda \Delta t$  by  $n$  power  $n - k$ .

So this is the way, I can able to get what is the probability that  $K$  arrival takes place in the interval zero to  $t$  by partitioning  $n$  intervals, so this is the probability. But the way I made a partition  $n$  equal parts, so now I have to go for what is the result as  $n$  tends to infinity. That means my interest is, what could be the result, if  $n$  tends to infinity of  $k$  of, what is the probability that  $N(t)$  takes a value  $K$ , as  $N$  tends to infinity.

Therefore, the running index for  $K$  is going to be 0, 1, 2 and so on. What is the probability of  $N(t)$  takes a value  $K$ . That means in the right hand side, I had to go for finding out, as  $N$  tends to infinity what is the result for the right hand side, what is the probability of  $N(t)$  takes the value  $K$ . We take  $N$  tends to infinity because we need to study the limiting behavior of the stochastic process.

So that is same as limit  $N$  tends to infinity of  $\binom{n}{k} p^k (1-p)^{n-k}$ , I can make it as  $p^k (1-p)^{n-k}$ , where  $p$  is going to be  $\lambda \Delta t$  and one minus  $p$  power  $n - k$ . Now I have to find out what is the result for limit  $N$  tends to infinity of this expression  $\binom{n}{k} p^k (1-p)^{n-k}$ , where  $p$  is going to be  $\lambda \Delta t$ .

**(Refer Slide Time: 09:46)**

$$\begin{aligned}
&= \lim_{n \rightarrow \infty} \frac{n!}{(n-k)! k!} \left(\frac{\lambda t}{n}\right)^k \left(1 - \frac{\lambda t}{n}\right)^{n-k} \\
&= \lim_{n \rightarrow \infty} \frac{n!}{n^k (n-k)!} \frac{(\lambda t)^k}{k!} \underbrace{\left(1 - \frac{\lambda t}{n}\right)^n}_{e^{-\lambda t}} \cdot \underbrace{\left(1 - \frac{\lambda t}{n}\right)^{-k}}_1 \\
&= \frac{(\lambda t)^k}{k!} \cdot e^{-\lambda t} \\
P(N(t) = k) &= e^{-\lambda t} \frac{(\lambda t)^k}{k!}, \quad t = 0, 1, 2, \dots \\
\text{For fixed } t, & \\
N(t) &\sim \text{Poisson distribution } (\lambda t) \\
&|N(t), t \geq 0| \text{ P.P}
\end{aligned}$$

If I do this simple calculation, let me explain, the limit  $n$  tends to infinity that is same as limit tends to infinity of  $n^k$ , I can make it as a  $n$  factorial,  $n$  minus  $k$  factorial and  $k$  factorial and that is  $\lambda t$  by  $n$  power  $k$  and that is one minus  $\lambda t$  by  $n$  power  $n$  minus  $k$  and that is same as the limit  $n$  tends to infinity of  $n$  factorial. And here this  $n$  power  $k$ , I can take it outside. And  $n$  minus  $k$  factorial and  $\lambda t$  power  $k$  and divided by  $k$  factorial. So this  $k$  factorial I take it inside.

And the power one minus  $\lambda t$  by  $n$  power  $n$  minus  $k$ , I split it into one minus  $\lambda t$  by  $n$  power  $n$  into one minus  $\lambda t$  by  $n$  power minus  $k$ . So, now I can look as  $n$  tends to infinity this is nothing to do with  $n$ . Therefore,  $\lambda t$  power  $k$  by  $k$  factorial will come out. So this result is going to be  $\lambda t$  power  $k$  by  $k$  factorial. And this will land up as  $n$  tends to infinity. This is going to be  $e$  power minus  $\lambda t$  and this will land up one and this is also land up one as  $n$  tends to infinity. Therefore, I may land up it is  $e$  power minus  $\lambda t$ .

Hence the final answer of what is the probability that  $k$  arrival takes place in the interval zero to  $t$  that is going to be  $e$  power minus  $\lambda t$  and the  $\lambda t$  power  $k$  by  $k$  factorial. And the possible values of  $k$  can be 0, 1, 2 and so on. For fixed  $t$ , if you see this is same as, for fixed  $t$  it is going to be a random variable. For all possible values of  $t$ , it is going to be a stochastic process.

So for fixed  $t$ , the  $N(t)$  is a random variable and that probability mass function is  $e^{-\lambda t} \frac{(\lambda t)^k}{k!}$ . So  $\lambda$  is a constant. For fixed  $t$ ,  $\lambda t$  is a constant. Therefore, the right hand side looks like the probability mass function of the Poisson distribution. Therefore, for fixed  $t$ , the  $N(t)$  is Poisson distribution. The random variable  $N(t)$  for fixed  $t$ , it is going to be a Poisson distribution with the parameter  $\lambda t$ .  $\lambda$  is a constant.

And for fixed  $t$ ,  $t$  is a constant. So  $\lambda t$  is a constant. Therefore, for fixed  $t$ , it is going to be a Poisson distribution with the parameter  $\lambda t$ . Therefore, for possible values of  $t$ , the  $N(t)$  is going to form a stochastic process. And since for fixed  $t$ , it is going to be a Poisson distribution, the collection of a random variable and each random variable is a Poisson distribution.

Therefore, this is going to be called it as the Poisson process. The way I have, we have explained earlier, each random variable is a Bernoulli distributed random variable, the collection of random variable is a Bernoulli process, similarly each  $s_n$  is going to be a binomial distribution, therefore the collection is going to be a binomial process. The same way, for fixed  $t$ , it is going to be a Poisson distribution, therefore the collection is going to be called it as the Poisson process.

So now we have developed  $N(t)$  is going to be a Poisson process.
