**Stationary Distribution and Examples**

Now I am going to move the Stationary Distribution, the stationary distribution also a very important concept in the Markov chain and as such first I am going to give the definition of a stationary distribution.

**(Refer Slide Time: 00:21)**

Definition

The vector  $\pi$  is called a stationary distribution of the DTMC if  $\pi = (\pi_0, \pi_1, \pi_2, \dots)$  satisfies

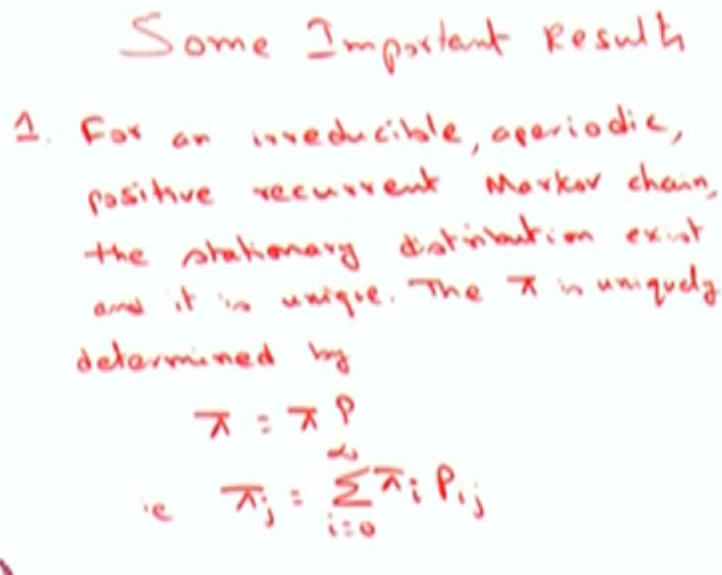

- (1)  $\pi_j \geq 0 \forall j$
- (2)  $\sum \pi_j = 1$
- (3)  $\pi = \pi P$

The vector  $\pi$  is called a stationary distribution of a time homogeneous discrete time Markov chain, if that vector satisfies the first condition, all these values  $\pi_j$ 's are greater than or equal to 0 for all  $j$  and the summation over  $\pi_j$ 's that is going to be 1, and the third condition  $\pi$  is going to be same as the  $\pi$  times  $P$ , where  $P$  is the one step transition probability matrix. So any vector  $\pi$  satisfies these three conditions.

Then, that vector is going to be call it as a stationary distribution, this is a nothing to do with the limiting distribution the one I have discussed earlier, but for an irreducible aperiodic Markov chain the limiting distribution is same as the stationary distribution that is also going to be same as the equilibrium or a steady state distribution. All these three distributions are going to be same for a irreducible aperiodic Markov chain.

But, for in general, all these three things are going to be different, so here I am giving the definition of a stationary distribution by satisfying these three properties.

(Refer Slide Time: 01:54)

Now I am going to give some important results for that, the first result is for an irreducible aperiodic a positive recurrent Markov chain the stationary distribution exists and it is unique, the one definition I have given earlier, I have discussed aperiodic irreducible I have to include the positive recurrent also. Because these three things are important for an irreducible aperiodic a positive recurrent Markov chain all these three distributions limiting distribution, stationary distribution, steady state or equilibrium distribution, all three are same.

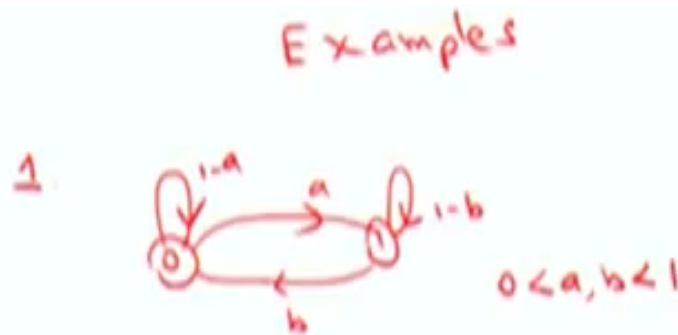

I have to include the positive recurrent also, so what I am giving in this result then  $\pi_i$  is uniquely determined by solving this equation  $\pi_i$  equal to  $\pi_i P$  with the summation of a  $\pi_i$ 's are going to be 1. So if I solve  $\pi_i$  is equal to  $\pi_i P$  along with the summation of  $\pi_i$  is equal to 1 that will give a unique  $\pi_i$  and that  $\pi_i$  is going to be a stationary distribution for a irreducible aperiodic positive recurrent Markov chain, irreducible means all the states are communicating with all other states.

Aperiodic means the periodicity for a state is a 1, the greatest common divisor of a system coming back to the same state all the possible - possible steps that greatest common divisor is 1. The positive recurrent means it's a recurrent state that means with the probability 1, the system

start from one state and coming back to the same state that probability is 1, the positive recurrent means, the mean recurrence time that is going to be a finite value.

If these three conditions are going to be satisfied by any discrete - time homogeneous discrete time Markov chain. Then the stationary distribution can be computed using  $\pi$  is equal to  $\pi P$  and the summation is equal to 1 that is going to be a unique value.

**(Refer Slide Time: 04:11)**

I am giving the same example - I am giving the same example that is the two state model with states 0 and 1 with probability is a self-loop 1 minus a and self-loop 1 minus b and the system going from the state is 0 to 1 in one step that is a and the system is going from the state 1 to 0 that probability is b, so I am giving a very simple two state model and you can solve  $\pi$  is equal to  $\pi P$  and summation is equal to 1 and you will get the probabilities.

And these probabilities are same as the probability is you got it in the limiting state probability, if you solve.

**(Refer Slide Time: 05:17)**

$$\lim_{n \rightarrow \infty} P^n = \begin{pmatrix} \frac{b}{a+b} & \frac{a}{a+b} \\ \frac{b}{a+b} & \frac{a}{a+b} \end{pmatrix}$$

Limiting distribution vector

$$\pi = (\pi_0, \pi_1)$$

Note that  $\pi_0, \pi_1$  are independent of initial state 'i'

If you solve the two state model with the  $\pi_i$  is equal to  $\pi_i P$ , you will get the probability is that  $\pi_0$  is going to be  $b$  divided by  $a + b$  and  $\pi_1$  is going to be  $a$  divided by  $a + b$ , and it satisfies the summation of  $\pi_i$  is equal to 1 and it also satisfied  $\pi_i$  is equal to  $\pi_i P$ , that means in this model it is irreducible aperiodic positive recurrent model, therefore the limiting distribution is same as the stationary distributions also.

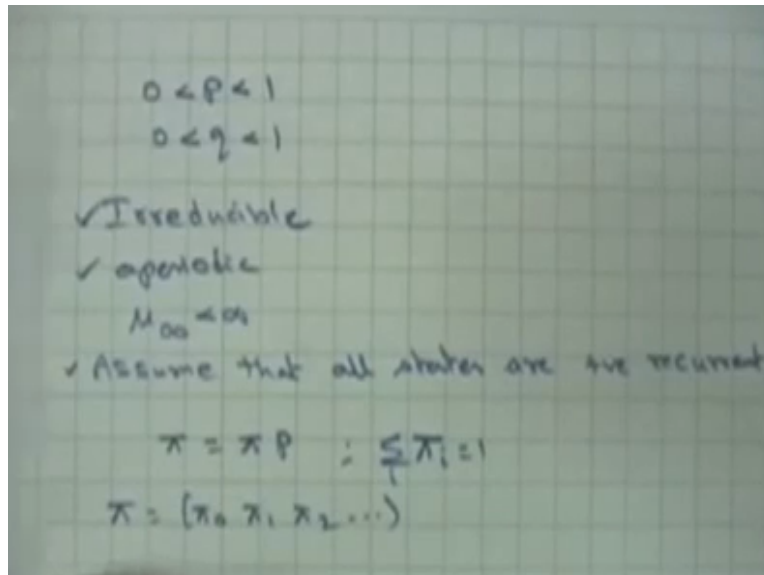

(Refer Slide Time: 05:53)

The second example, that is with the infinite state so here the number of states are going to be a countably infinite, I can start with the to find out the stationary distributions before that I have to cross check whether it is going to be irreducible aperiodic positive recurrent Markov chain, it is

irreducible because the way I have given the probabilities. I make the assumption the probabilities are lies between 0 to 1.

**(Refer Slide Time: 06:39)**

And the probability of lies - the q is also lies between 0 to 1, therefore each state is communicating with each other state, therefore it is going to be a irreducible, the second one it is it has to be aperiodic, aperiodic means the periodicity for each states, because the greatest common divisor is going to be 1, because the coming back to the state is via self-loop are going to the some other state and coming back and their also has a self-loop.

Therefore, it is going to be all the states are going to be aperiodic, therefore the Markov chain is aperiodic. The third one positive recurrent, since it is a infinite state model you cannot get the you cannot come to the conclusion whether these  $\mu_{00}$  is going to be a finite quantity unless otherwise substituting the value of a p and q.

So what I will do I will make the assumption assume that all states are positive recurrent then later I will find out what is the condition to be a positive recurrent, so I make the assumption even I do not want to make the - I do not want to make the assumption for all the states are going to be positive recurrent I can make the assumption for only 1 state is going to be positive recurrent and since it is a irreducible Markov Chain and all the states are going to be of the same type.

Therefore, it will come to the conclusion all the states are going to be a positive recurrent so I make the assumption one state is going to be positive recurrent therefore it lands up all the states are going to be a positive recurrent, now once I made a assumption of all the states are positive recurrent therefore it satisfies all the results of a the first result that is a irreducible aperiodic positive recurrent Markov chain with the infinite state space.

Therefore, I can find out the I can come to the conclusion the limiting distribution sorry, the stationary distribution exists and it is going to be unique and that can be computed by solving the equation  $\pi_i$  is equal to  $\pi_i P$  with the summation of  $\pi_i$  is equal to 1, where  $\pi_i$  is the vector and  $P$  is the one step transition probability matrix, that one step transition probability matrix can be created using the state transition diagram which I have given.

So if I take the - if I find out what is the first equation from this vector  $\pi_i$  is equal to  $\pi_i$  naught,  $\pi_1$ ,  $\pi_2$  and so on, here also this and  $P$  is the matrix.

**(Refer Slide Time: 10:00)**

$$\begin{aligned} \pi_0 &= \pi_0(1-p) + \pi_1 q \\ &\Rightarrow \pi_1 = \frac{p}{q} \pi_0 \\ \pi_1 &= \pi_0 p + \pi_1(1-p-q) + \pi_2 q \\ &\Rightarrow \pi_2 = \frac{p^2}{q^2} \pi_0 \\ \pi_3 &= \frac{p^3}{q^3} \pi_0 \\ \pi_n &= \frac{p^n}{q^n} \pi_0, \quad n=1,2,3,\dots \end{aligned}$$

Therefore, I will get the first equation as  $\pi_0$  is equal to  $\pi_0$  times 1 minus  $p$  +  $\pi_1$  times  $q$ , so this is the first equation of a, from the matrix  $\pi_i$  is equal to in the matrix form  $\pi_i$  is equal to  $\pi_i P$ , so the first equation is  $\pi_0$  is equal to  $\pi_0$  times 1 minus  $p$  +  $\pi_1$  times

$q$ , so from this equation I can get  $\pi_1$ , because I can take this  $\pi$  naught this side and I can cancel, so I will get a  $\pi_1$  is equal to  $p$  divided by  $q$  times  $\pi$  naught.

From the first equation we get the relation  $\pi_1$  in terms of  $\pi$  naught, now I will take a second equation from  $\pi$  is equal to  $\pi^p$ , so that will give  $\pi_1$  is equal to  $\pi$  naught times  $p + \pi_1$  times  $1$  minus  $p$  minus  $q + \pi_2$  times  $q$ , so this equation have  $\pi$  naught,  $\pi_1$  and  $\pi_2$ , so what I can do I can write  $\pi_1$  in terms of  $\pi$  naught and I can simplify this equation if I simplify, I will get  $\pi_2$  is same as  $p$  square by  $q$  square times  $\pi$  naught.

Because I am substituting  $\pi_1$  in terms of  $\pi$  naught, in this equation therefore I get  $\pi_2$ , in terms of  $\pi$  naught, that is  $\pi_2$  is equal to  $p$  square by  $q$  square times  $\pi$  naught. Similarly, if I take the third equation and do the same thing finally, I get  $\pi_3$  is equal to  $p$  cube by  $q$  cube  $\pi$  naught, the same way I can go further therefore I am get  $\pi_n$  in terms of  $\pi$  naught, for  $n$  is equal to  $1$   $2$   $3$  and so on.

So this is the way I can solve this equation  $\pi$  is equal to  $\pi^p$  that is a homogeneous equation we have to be very careful with the homogeneous equation, so that trivial solutions are going to be  $0$ , but we are try to find out the non-trivial solutions therefore we are using the normalization that is the summation of  $\pi$  is equal to  $1$ , till now I have not use, so I have - I have just simplified that  $\pi$  is equal to  $\pi^p$  and getting  $\pi_n$  in terms of  $\pi$  naught.

**(Refer Slide Time: 13:02)**

$$\sum_{i=0}^{\infty} \pi_i = 1$$

$$\pi_0 \left( 1 + \frac{p}{q} + \frac{p^2}{q^2} + \dots \right) = 1$$

$$\pi_0 = \frac{1}{1 + \frac{p}{q} + \frac{p^2}{q^2} + \dots}$$

$$\frac{p}{q} < 1$$

$$\pi_n = \left( \frac{p}{q} \right)^n \pi_0 \quad \therefore \frac{p}{q} < 1$$

Now I have to use summation of a  $\pi_i$  is equal to 1 starting from  $i$  is equal to 0 to infinity therefore the  $\pi_0$  will be out  $1 + p$  by  $q + p$  square by  $q$  square and so on, that is equal to 1, therefore the  $\pi_0$  is going to be 1 divided by  $1 + p$  by  $q + p$  square by  $q$  square and so on, that is  $\pi_0$ , since it is a infinite terms in the denominator as long as this is converges you will get a non-zero value for a  $\pi_0$ .

Intern you will get a  $\pi_i$  is equal to  $p$  by  $q$  power  $n$  times  $\pi_0$  provided this denominator is going to be converges, when the denominator is going to be converges in this situation as long as the  $p$  by  $q$  is going to be less than 1, if  $p$  by  $q$  is less than 1 earlier condition is  $p$  is lies between 0 to 1 and  $q$  is lies between 0 to 1, now I am making the additional condition  $p$  by  $q$  is less than 1 that will ensure the denominator converges therefore the  $\pi_0$  is going to be a non-zero value.

Therefore, the  $\pi_n$ 's are going to be  $p$  divided by  $q$  power  $n$  times  $\pi_0$ , where  $\pi_0$  is written 1 divided by  $1 + p$  by  $q + p$  by  $q + p$  by  $q$  whole square and so on, so provided  $p$  by  $q$  is less than 1, if you recall we made the assumption the states are going to be a positive recurrent, if this  $p$  by  $q$  is less than 1, then you can conclude the mean recurrence time is going to be a finite value.

If you make the assumption  $p < q$  that will ensure the mean recurrence time for any state is going to be a finite value therefore all the states are going to be positive recurrent and then the stationary distribution exists therefore this is the condition for a positive recurrent state for this model and the stationary distributions that is going to be  $\pi_n$  is equal to  $p^n$  times  $\pi_0$ .

This is nothing but in a longer run what is the probability that the system will be in the state  $n$  that probability is  $p^n$  times  $\pi_0$  and  $\pi_0$  is given in this form, and in this example we have taken each state for the  $p < q$  is same for all the states we can go for - go for a in general situation the system going from 0 to 1 could be  $\pi_0$ , system going from the state 1 to 2 maybe  $p$  and so on.

Therefore, it need not all the  $\pi_i$ 's need not be same and the  $q$  is also not be same so you can generalized this model and this model is nothing but a one dimensional random walk and here the 0 is it's a barrier the system is not going away from the 0 in the left side therefore 0 is the barrier and this is a one dimensional random walk in which the system is a keep moving into the different states in subsequent steps.

And there is a possibility the system may be in the same state with the positive probability of  $1 - p - q$  in this model, in general you can go for the  $p, \pi_0, p^1, p^2$  and so on, and similarly,  $q^1, q^2, q^3$  and so one also.
