2. With one or more absorbing states

- Further, assume that finite state and all the recurrent states are absorbing states.
- Canonical form

$$P = \begin{matrix} & \begin{matrix} A & T \end{matrix} \\ \begin{matrix} A \\ T \end{matrix} & \begin{pmatrix} I & 0 \\ R & Q \end{pmatrix} \end{matrix}$$

$S = A \cup T$   
A: the set of absorbing states  
T: the set of transient states

Now we are moving into the second type, in the second type this is a reducible Markov Chain, but here each close communicating class consists of only one element that is nothing but the absorbing states but more than one communicating class are possible, therefore this type is called with one or more absorbing states, here also my interest is to find out the stationary distribution. The stationary distribution here the interests are of the different way.

One is the probability of the absorption, the other one is the what is the mean time before absorption, so for that I'm making further assumption the state space is going to be finite, so with the time making Canonical form. The Canonical form consists of all the absorbing states that I label it as capital A and all the transient states are capital T. Therefore, the state space S is a A union capital T.

Therefore, the Canonical form I collect all the absorbing states in the first few rows and then remaining will be the all the transient states, since the absorbing states  $P_{ii}$  is equal to 1,

therefore you will have a identity matrix for the sub matrix of the matrix P corresponding to A to A. Whereas A to T absorbing states to the transient states that elements are going to be zero.

So that is the submatrix with the entities zero, whereas T to A will be some matrix capital R and T to T will be sub matrix Q.

**(Refer Slide Time: 01:59)**

Here,

$$P^n = \begin{matrix} & A & T \\ A & \begin{pmatrix} I & 0 \\ R_n & Q^n \end{pmatrix} \end{matrix}$$

As  $n \rightarrow \infty$

$$Q^n \rightarrow 0 \Rightarrow \lim_{n \rightarrow \infty} P_{ij}^{(n)} = 0 \quad \forall i, j \in T$$

So if you go for what is the n step transition probability since it is identity matrix again also you will have identity matrix, whereas T to A that is going to be a function of n whereas T to T, will be a power n that is Q Rise to power n, as n tends to infinity the system won't be in the transient states therefore Q n will tend to zero submatrix as n tends to infinity, and these probabilities are going to be zero for all i, j belonging to T, T is nothing but the set of transient states.

**(Refer Slide Time: 02:39)**

**Probability of Absorption**

$$P_{ik}^{(n+1)} = \sum_{j \in S} P_{ij} P_{jk}^{(n)} \quad ; \quad \begin{matrix} i \in T \\ k \in S-T \end{matrix}$$

Use  $P_{kk} = 1$ ;

$$P_{ik}^{(n+1)} = P_{ik} + \sum_{j \in T} P_{ij} P_{jk}^{(n)} \quad - (1)$$

Define  $a_{ik} = \text{Prob} \left\{ \begin{array}{l} \text{system starts in state 'i'} \\ \text{eventually gets absorbed} \\ \text{in an absorbing state k} \end{array} \right\}$

As  $n \rightarrow \infty$  in (1),

$$a_{ik} = P_{ik} + \sum_{j \in T} P_{ij} a_{jk}$$

Our interest is here what is the probability of absorption? Because we have a few one or more absorbing states so if the system starts from some transient state what is the probability that the system will be absorbed into these absorption state, so for that I am going to start with the Chapman Kolmogorov equation. That's Chapman Kolmogorov equation for the  $n + 1$  th step the system going from the state  $i$  to  $k$ .

That probability same as what are all the possible the system can go make a one step from  $i$  to  $j$  and then  $j$  to  $k$  in  $n$  steps all the possibilities  $j$  belonging to  $S$ , where  $S$  is the state space. I know either I have a one sorry, either I have a transient states or all other states are absorbing states. Therefore, if  $k$  is going to be the absorbing state then  $P_{kk}$  is equal to 1, that means a one-step transition probability of system moving from state  $k$  to  $k$  that is 1.

Therefore,  $i$  to  $k$  in  $n + 1$  steps that probability I can split I can make  $i$  to  $k$  in one step then forever  $i$  will be in the state  $k$  plus  $i$  would have move to the state  $i$  to  $j$ , where  $j$  is another transient state it could be same also - could be same also then  $j$  to  $k$  in  $n$  steps. Now I am defining what is the meaning of probability of absorption? That I am denoting with the letter  $A$  suffix  $i, k$  that is nothing.

But the probability that the system starts in state  $i$  it starts in state  $i$  eventually get absorbed in a absorbing state  $k$ , so the first letter is the starting state and the second  $k$  is the absorbing state, so

this is a probability of absorption starting from the state  $i$  to the absorption state  $k$ . Now, I am taking the equation 1 as I make  $n$  tends to infinity in both side the, left hand side will be  $a_{i,k}$  because as  $n$  tends to infinity so this will be  $a_{i,k}$ , similarly  $p_{j,k}$  of  $n$  that is also  $a_{j,k}$ .

Therefore, I will have  $a_{i,k}$ , this side and  $a_{j,k}$ , so this is sort of recursive equation so this is in the element form I can go for in the matrix form.

**(Refer Slide Time: 05:35)**

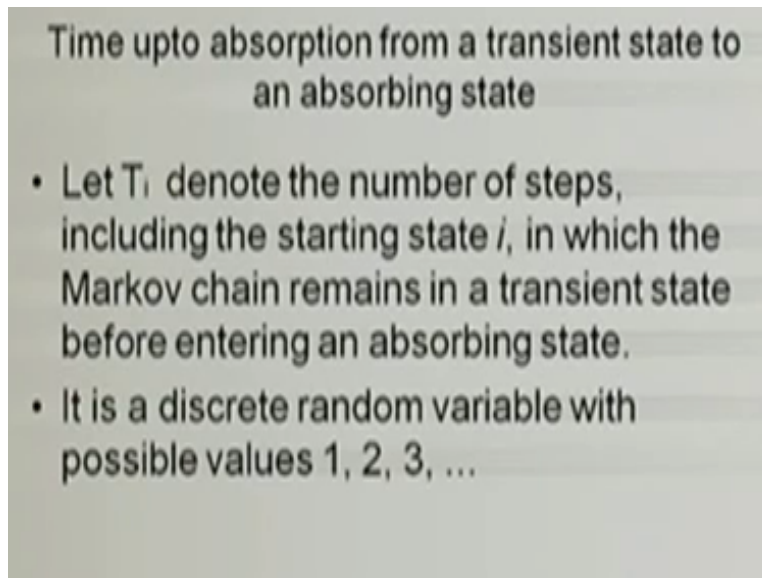

In matrix form  
 $A = [a_{ik}]$   
 $A = R + QA$   
 $A = [I - Q]^{-1}R$   
 $[I - Q]^{-1}$  - fundamental matrix.  
 The probability of absorption is not independent of the initial state 'i'.

So I can write  $a_{i,k}$  as a matrix capital  $A$ , therefore in the matrix form the previous this equation for all values of  $i$  this equation as in the matrix form capital  $A$  is equal to  $R$  matrix, because this  $P_{i,k}$  where  $i$  is the transient state and  $k$  is the absorbing state so transient state to the absorption state - transient state to the absorption state that submatrix is capital  $R$ .

Therefore, in the matrix form capital  $A$  is equal to  $R$  matrix +  $Q$  matrix that is a the one step transition of system is moving from transient to transient multiplied by  $A$  matrix so I can do the simplification so I get  $A$  matrix equals to  $I$  minus  $Q$  inverse  $R$  matrix, and here this  $I$  minus  $Q$  inverse that is nothing but the fundamental matrix. So once you are able to calculate find out the fundamental matrix multiplied by the  $R$  matrix that will give the probability of absorption starting from the transient state and reaching absorption state.

And these probabilities not independent of initial state that is very important whereas the previous type of reducible Markov chain that is a independent of initial state whereas here the probability of absorption is not independent of the initial state  $i$ . So this you can visualize through one example that I am going to present later.

**(Refer Slide Time: 07:29)**

Time upto absorption from a transient state to an absorbing state

- Let  $T_i$  denote the number of steps, including the starting state  $i$ , in which the Markov chain remains in a transient state before entering an absorbing state.
- It is a discrete random variable with possible values 1, 2, 3, ...

The next result interested in the reducible Markov chain with one or more absorbing states that is a what is the time to absorption? Basically our interest to get the meantime to absorption starting from the transient state to a absorption state, that means how much time on average the system is spending in the transient states before absorption that is very important.

Because many application has reducible Markov chain in which more than one absorption states are there with the transient state therefore what is the mean time up to absorption that means how much time spending in the transient states before the absorption so for that I am going to define the random variable capital  $T_i$ . The  $T_i$  denotes the number of steps including the starting state  $i$  in which the Markov chain reminds in a transient state before entering a absorption state.

So there is a possibility the system would have been spending at least one step before absorption or two steps or three steps and so on, therefore that is going to be a random variable it is a discrete random variable with the possible values are 1 2 3 and so on. Our interest is not only

finding out the distribution of  $T_i$ , our interest is to find out what is the mean time up to absorption, from the transient state to an absorbing state.

**(Refer Slide Time: 09:17)**

$$\begin{aligned}
 \text{Prob}\{T_i = n\} &= \text{Prob}\{T_i \geq n-1\} - \text{Prob}\{T_i \geq n\} \\
 &= \text{Prob}\{X_{n-1} \in T\} - \text{Prob}\{X_n \in T\} \\
 &= \sum_{j \in T} (P_{ij}^{(n-1)} - P_{ij}^{(n)}) \\
 \text{For } i, j \in T \quad P_{ij}^{(n)} &= Q^n \\
 \text{Hence,} \quad \text{Prob}\{T_i = n\} &= Q^{n-1} (I - Q)e \\
 \text{Mean time} \quad \mu &= (I - Q)^{-1}e
 \end{aligned}$$

So this probability can be computed by finding out what is the probability of  $T_i = n$  for some  $n$ ,  $n$  can take the values 1, 2, 3, and so on. So that discrete random variable probability mass function can be computed in this way you find out what is the probability of  $T_i$  is greater than or equal to  $n-1$  minus what is the probability that  $T_i$  is greater than or equal to  $n$ .

If you find the difference that is same as the probability mass at  $n$ , but this is same as the  $T_i$  greater than or equal to  $n-1$ , that is same as the  $(n-1)$ th step the system is in the transient state, if  $T_i$  is going to be greater than or equal to  $n-1$ , that means the system spends at least  $(n-1)$  steps in the transient states once it goes to the absorbing state then it need cannot come back to the transient states.

Therefore, the meaning of  $T_i$  greater than or equal to  $(n-1)$  that is same as the  $(n-1)$ th step the system in the transient states, so both the events are equivalent, therefore the probabilities are equal similarly, you can argue  $T_i$  greater than or equal to  $n$  means at least  $n$  steps the system in the transient state before absorption, that is same as in the  $n$ th step the system is in the transient state.

The probability of  $n - 1$ th step the system is in the transient state that is same as what is the what are all the possibilities the system would have move from state  $i$  to  $j$  in  $n - 1$  steps, you add all the possibilities  $j$  belonging to  $T$ , you add all the possibilities of the transient states that summation will give this probability similarly, for the  $X_n$  belonging to capital  $T$ , this is in the for fixed  $i$ , where  $i$  is belonging to the transient state.

now I will go for I know that for  $i, j$  belonging to  $T$ , the  $n$  step transition probability is nothing but the submatrix that is  $Q$  power  $n$ , if you recall the way we made Canonical form of a  $P$  matrix the  $T$  to  $T$ , that is a  $Q$  matrix, therefore as  $n$  tends to for any  $n$ th step that is going to be  $Q$  power  $n$ , so this is what I am using for  $i, j$  belonging to capital  $T$  the sub matrix of  $P$  power  $n$  that is  $Q$  power  $n$ .

Therefore, for  $i, j$  belonging to  $T$ , the  $n$  step transition of system moving from  $i$  to  $j$  that is  $Q$  power  $n$ , therefore I can substitute here in the above equation so the probability mass at  $n$  that is same as  $Q$  power  $n - 1$  into  $I - Q$  into  $e$  vector, once I know the probability mass function for the discrete random variable  $T_i$  then I can find out the mean, mean is nothing but summation  $n$  times the probability mass at  $n$   $T_i$  is equal to  $n$ .

If I add submission over  $n$ , that is going to be the meantime up to absorption that is going to be do the simple calculation you will get a  $I - Q$  inverse into  $e$  vector, this  $I - Q$  inverse is nothing but the fundamental matrix that means if you find out the fundamental matrix multiplied by the  $R$  sub matrix you will get the probability of absorption if you multiplied by the  $e$  vector you will get the meantime up to the absorption.
