Example 2

Let $\{N(t), t \geq 0\}$ be a Poisson process with intensity λ and $\{\mathcal{F}(t), t \geq 0\}$ its natural filtration.

$$\begin{aligned} E(N(t) | \mathcal{F}(s)) &= E(N(t) - N(s) + N(s) | \mathcal{F}(s)) \\ &= E(N(t) - N(s) | \mathcal{F}(s)) + E(N(s) | \mathcal{F}(s)) \\ &= \lambda(t - s) + N(s) \end{aligned}$$

Hence,

$$E((N(t) - \lambda t) | \mathcal{F}(s)) = (N(s) - \lambda s)$$

Therefore, $\{N(t) - \lambda t, t \geq 0\}$ is a martingale.

The second example, this stochastic process is a continuous-time discrete state stochastic process. So here let $N(t)$ where t varies from 0 to infinity be a Poisson process with the intensity λ or parameter λ and the $F(t)$ is its natural filtration. The natural filtration means it has the information till time t and each random variable $N(t)$ for fixed t is $F(t)$ measurable. That is the meaning of a natural filtration.

We know that for fixed t , $N(t)$ is a Poisson distributed random variable with the parameter λ . Therefore, the mean of $N(t)$ that is same as the parameter λ . So the first condition is satisfied.

The second condition, for fixed t , $N(t)$ has to be $F(t)$ measurable. Since it is a natural filtration, the $N(t)$ is a $F(t)$ measurable.

The third condition we are going to verify. The conditional expectation of $N(t)$ given $F(s)$ where $F(s)$ is the filtration at time s or the information till s . Obviously, here s is less than t .

So to find out this conditional expectation, what we do? We add and subtract $N(s)$ with the $N(t)$. So instead of a conditional expectation of $N(t)$ given $F(s)$, we subtract $N(s)$ and add $N(s)$.

Expectation is a linear operator. Therefore, you can split this, these three terms into two different expectations, conditional expectations. Therefore, the first one you can keep $N(t) - N(s)$. The second one you can keep it separately $N(s)$. Hence, you have conditional expectation of $N(t) - N(s)$ given the filtration $F(s)$ plus conditional expectation of $N(s)$ given $F(s)$.

In the first term, the first term, this conditional expectation is nothing but you know the information till time s and we are asking the conditional expectation of $N(t) - (s)$ given $F(s)$. That means this t minus s and s , this is a non-overlapping intervals. S is the point. T minus s is the non-overlapping intervals. So this is the random variable corresponding to the non overlapping interval with respect to s .

Therefore, non -- you know the property of Poisson process. For s less than t , $N(t) - N(s)$ is nothing but the increments. The increments are stationary and independent. Therefore, the $N(t) - N(s)$ is independent of $F(s)$. If it is independent, the conditional expectation is nothing but expectation of $N(t) - N(s)$. You know the Poisson process, the properties. Since $N(t)$ is a Poisson process, $N(t) - N(s)$ for a fixed t and s , this is a Poisson distributed random variable with the mean λ times $(t-s)$.

Therefore, this conditional expectation will be λ times $(t-s)$ based on the $N(t) - N(s)$ is independent of $F(s)$ and for fixed s and t , $N(t) - N(s)$ is a Poisson distributed random variable with the mean λ times $(t-s)$ whereas the second term, conditional expectation of $N(s)$ given $F(s)$ that means for information till time s , what is the expectation of $N(s)$ at the same time s ? So since you know the information till or up to the time s , $N(s)$ is constant. $N(s)$ is a constant.

Therefore, expectation of constant is a constant. Therefore, it is $N(s)$. It's not a λ times s because you know the information till time s . Once you know the information till time s , that means you know the value of $N(s)$ also. Once you know the value of $N(s)$, therefore, $N(s)$ is no more a random variable. So it's a constant. So expectation of a constant is a constant. So it is $N(s)$.

Hence, conditional expectation of $N(t)$ given $F(s)$ is same as you can take λt in this side, so conditional expectation of $N(t) - \lambda t$ given $F(s)$ is same as $N(s)$ minus λ times s . You see this is the expectation of $N(t) - \lambda s$ given $F(s)$. That is same expression. Therefore, as such expectation of $N(t)$ given $F(s)$ is not $N(s)$. It has the some positive value. $(t - s)$ is always greater than 0. Therefore, λ times $(t - s)$ will be greater than 0. Therefore, this conditional expectation is always greater than or equal to $N(s)$.

Hence, $N(t)$ is not a Martingale whereas if you treat $N(t) - \lambda t$ as a stochastic process over the t ranges from 0 to infinity, then this stochastic process is a Martingale. The $N(t)$ is not satisfying is same as $N(s)$. The conditional expectation is not equal to $N(s)$, but it is greater

than or equal to $N(s)$. Therefore, $N(t)$ is not a Martingale whereas if you make another stochastic process, that is nothing but $N(t) - \lambda$ times t for t greater than or equal to 0, then this stochastic process satisfies the third condition and also satisfies the other two conditions. Therefore, the $N(t) - \lambda t$ is a Martingale.

Example 3

Consider the binomial tree model. Let $\{S_n, n = 0, 1, \dots\}$ be a stochastic process and $\{\mathcal{F}_n, n = 0, 1, \dots\}$ be the natural filtration.

$$P(S_{n+1} = uS_n | \mathcal{F}_n) = p \quad \text{and} \quad P(S_{n+1} = dS_n | \mathcal{F}_n) = 1 - p$$

Consider the discounted process $\{S_0, e^{-r}S_1, e^{-2r}S_2, \dots\}$. We have

$$E(e^{-(n+1)r}S_{n+1} | \mathcal{F}_n) = ue^{-(n+1)r}S_n p + de^{-(n+1)r}S_n(1 - p)$$

where r is the riskless interest rate.

The discounted process is a martingale only if the right hand side is equal to $e^{-nr}S_n$. This is the case only if $p = \frac{e^r - d}{u - d}$. Since $0 < p < 1$, if $d \leq e^r \leq u$, then the discounted process is a martingale.

Third example. This is related to the application of finance. Consider the binomial tree model. Let S_n be a stochastic process and the \mathcal{F}_n be the -- its natural filtration. Define the probability of S_{n+1} given u times S_n given \mathcal{F}_n that is same as -- that is p and the probability of S_{n+1} is equal to d times S_n given \mathcal{F}_n is equal to $1 - p$ where u and d are the next value of S_n with the probability p and q respectively.

Therefore, suppose the previous, the n^{th} value was S_n , then the next value will be, it is decremented with d , therefore, d times S_n or it would have been incremented with u . Therefore, u times S_n will be the S_{n+1}^{th} value. Therefore, this -- this stochastic process is called the binomial tree model.

Now I am considering the discounted stochastic process that is nothing but e power minus r times, basically $e^{-rt} S_t$. Since it is a discrete-time stochastic process, the first S_1 is multiplied by e^{-r} whereas the second random variable S_2 is multiplied by e^{-2r} and so on. Therefore, the n^{th} random variable S_n will be e^{-nr} where r is the riskless interest rate. So whenever you multiply the e^{-nr} times t , the corresponding stochastic process is called the discounted stochastic process.

The discounted stochastic process is a martingale if -- only if the right hand side is equal to $e^{-nr} S_n$ because here it is a conditional expectation of $e^{-(n+1)r} S_{n+1}$ given \mathcal{F}_n . If this quantity is same as e^{-nr} multiplied by S_n , then this discounted stochastic process will be a martingale or it has the martingale property.

So this is the case only if -- if the p value takes e^r times $-d$ and divided by u minus d if the p is the probability of incremented by u , if the p is equal to $e^r - d$ divided by $u-d$, then the discounted stochastic process is a Martingale. So that is possible because since p lies between 0 to 1, since the -- whenever the r is the riskless interest rate, e^r is also lies between d to u . Therefore, the $u - d$ and $e^r - d$, these values is going to be lies between 0 to 1. So, therefore, with the proper value of r , d and u , the p can be -- if the p is of this form, then the discounted stochastic process is a martingale.
