**Introduction to First Order Differential Equations**

Hello viewers. So welcome to this course. This is your first lecture. So we start with this lecture with the very basic differential equation that is a first order linear differential equation.

**(Refer Slide Time: 00:31)**

Lecture-1

first order linear differential Equation.

$$\frac{dy}{dx} = f(x,y) \quad \text{--- (1)}$$

Eq (1) can be defined as the simplest form

$$\frac{dy}{dx} = \text{Constant} = c \quad \text{--- (2)}$$

= integrate eq (2) both side  
w.r.t x  $\rightarrow \int \frac{dy}{dx} dx = \int c dx$

We know that a linear first order linear differential equation. So I start with the first order. So this is the simplest differential equation, first order differential equation,  $dy/dx = f(x, y)$  where  $y$  is a dependent variable and  $x$  is a independent variable and my function on the right hand side is a function of  $x$  and  $y$ . So we know that this differential equation we can solve by applying the method of integration if the right hand side function  $f(x, y)$  is integrable.

So I want to solve these differential equation. So I start with the simplest one. So I take the equation 1. Equation 1 can be, it can be defined as the simplest form. I have  $dy/dx$  is equal to some constant. That is equal to some  $c$  and I know that the constant  $c$  is a ([integrable](#)) function. So to solve this differential equation, what I do is I integrate equation (2) both side with respect to  $x$ . We get  $dy/dx$   $x$  is equal to integration of some constant  $cx$ .

**(Refer Slide Time: 02:51)**

$$\Rightarrow \boxed{y(x) = cx + d}$$

Now  $x = x_0 \Rightarrow y(x_0) = y_0$  (Initial value problems)

$$y(x_0) = cx_0 + d = y_0$$

$$\Rightarrow d = y_0 - cx_0$$

$$\Rightarrow y(x) = cx + y_0 - cx_0$$

$$\boxed{y(x) = c(x - x_0) + y_0}$$

$$y(x_0) = c(x_0 - x_0) + y_0 = y_0$$

Now we know that **by** with respect to  $d$   $x$ . Now, by the fundamental theorem of calculus, we know that on the left hand side we are taking the derivative and then integrating the function again. So from the left hand side we will get function  $y$   $x$  is equal to  $c$   $x$  plus constant of integration  $d$ .

So this is the solution of the differential equation 2, and I am able to solve this differential equation, because I am able to do the integration, where  $d$  is a constant of integration. Now this is the solution and for the different **different** values of the constant  $d$ , I can have different solutions. So in this case I can say that the solution exist and it has infinite many of solutions, because I can take the different values of  $d$  and I will get the different value of solutions.

**So** and if you see this is a equation of a line and if I take put equation of line. You put  $d = 1$  there is another line,  $d = -1$  there is another line. So these are all the isoclines we can draw and then it gives the family of the solutions. Now out of this family of the solution, suppose I want to take a solution, which starts with some points  $x = x$  naught.

So I define a condition that I want a solution which has, which start at the point  $x$  naught and it has initial value that is equal to  $y$  at  $x$  naught is a  $y$  naught. So such type of equation we know it is called initial value problems. So in the short form I will

write this as IVP. Now suppose I defined this one. So the above solution I can write as is equal to  $c$  at  $x$  naught plus  $d$  and that value is equal to  $y$  naught.

So from here I can define the value of  $d$  that is equal to  $y$  naught minus  $c$  naught. So my solution becomes  $y$  becomes  $c(x - x$  naught) +  $y$  naught, which can be further simplified and it becomes  $c(x - x$  naught) +  $y$  naught. So that is my solution. And this is a unique solution, which is starting from the point  $x$  naught. To verify this one I can put let us put in this case  $y$  at  $x$  naught.

So  $y$  at  $x$  naught become  $c(x$  naught -  $x$  naught) +  $y$  naught. So that becomes a  $y$  naught. So this is the solution corresponding to this initial condition. So after solving this equation, I will move further and I will try to make this differential equation, first order differential equation little bit harder by putting that  $dy/dx$  is equal to some function of  $x$ .

(Refer Slide Time: 06:29)

③ —  $\boxed{\frac{dy}{dx} = f(x) = \sin x = x^2 = e^x}$

Integration both side w.r.t  $x$

$$\int \frac{dy}{dx} dx = \int f(x) dx$$

$$\boxed{y(x) = \int f(x) dx + C}$$

IVP  $\boxed{y(x_0) = y_0}$

Where my  $f(x)$  is a function which is integrable. Integrable means which we can do the integration. It may be continuous or it will be a discontinuation then it has a finite number of discontinuities. So suppose I have  $f(x)$  maybe it can be  $\sin x$ , it can be  $x$  square, it can be exponential function, anything it can be. So I want to solve now the differential equation of this type.

Now I in this case also my function  $f(x)$  is integrable, then I will do the integration both side with respect to  $x$ . So my left hand side becomes  $dy/dx dx = f(x) dx$ . Now my

function is integrable. So this integration is possible, it will give you some finite solution and on the left hand side by the fundamental theorem of calculus, I will get  $y(x)$  on the left hand side becomes equal to the integration  $f(x) dx$  plus some constant of integration because on the left hand side I have taken the constant of integration.

So this is the solution of the differential equation 3. So in this case, this equation is also solvable because this is a linear equation and the right hand side function  $f(x)$  is integrable. So we are able to solve this differential equation in the same way and then if I apply the same initial value problem by putting some  $y(x_0) = y_0$ , then I am able to find the solution at I am able to find a unique solution by getting some value for this constant of integration  $c$ .

So this is also solvable for this initial value. I will write a general linear first order differential equation.

**(Refer Slide Time: 09:15)**

General first order linear diff. eq.

$$\frac{dy}{dx} + P(x)y = Q(x) \quad \text{--- (4)}$$

$P(x), Q(x)$  are continuous for  $x$

if  $Q(x) = 0$  then this is called homogeneous diff. eq.

$$\frac{dy}{dx} + P(x)y = 0 \quad \text{--- (5)}$$

$$\Rightarrow \frac{dy}{dx} = -P(x)y(x)$$

So first order, the general first order linear differential equation. So I start with the differential equation  $dy/dx$  plus some function  $P(x)y$  is equal to some function on the right hand side that is  $Q(x)$ . So in this case, I consider that my function  $P(x)$  and  $Q(x)$  are continuous, or continuous function of  $x$ . And we know that if the function are continuous, then they are **integrable**.

So this equation, this is the fourth equation. So if  $Q(x) = 0$  then this is called homogeneous differential equation. And then in that case, we are left with  $dy/dx +$

$P(x)y = 0$ . So in this case, if my  $Qx$  is 0 then I am able to solve I should be able to solve this differential equation. So this is the homogeneous first order linear differential equation. So I call it equation number 5.

Now from the from my previous knowledge, I was able to solve the differential equation, first order differential equation in which I have a function that is  $dy/dx$  equal to some function of  $x$  only. But in this case, I have  $dy/dx = -P(x)y(x)$ . So in this case on the right hand side, I have some product of two functions or I can have a functions which is dependent variable also appearing on the right hand side.

So let us see how to solve this type of differential equation. So in this case, how we will proceed. So let us do this one.

**(Refer Slide Time: 11:46)**

The image shows a handwritten derivation on a light pink background. It starts with the differential equation  $\frac{dy}{dx} = -P(x)y(x)$ . Then, it shows the equation divided by  $y(x)$  on both sides, resulting in  $\frac{dy}{y(x)} = -P(x)$ , with a note  $y(x) \neq 0$ . Below this, it says "Integrate both side w.r.t x". The next step is  $\int \frac{dy}{y(x)} dx = -\int P(x) dx$ . Finally, it shows the result:  $\ln |y(x)| = -\int P(x) dx + C$ , and then  $|y(x)| = e^{-\int P(x) dx + C}$ . There is a small red circular stamp on the left side of the final equation.

So I have this differential equation  $dy/dx = -P(x)y(x)$ . What I do is I take this function  $yx$  on the left hand side and on the right hand side, I have only this left with  $Px$ . So in this case, we are assuming that my  $yx$  is not equal to 0, because only then I am able to divide this one. Then I integrate both side with respect to  $x$ . So on the left hand side I have  $dy/dx$  divide by  $yx$ .

And on the right hand side I have  $-P(x) dx$ . Now on the left hand side what I have? I have the function and above that the numerator its derivative is there. So I know that the integration of this function can be written as log, log means it is I am taking the natural logarithm,  $yx = -P(x) dx$ . So that we know that how to integrate on the left

hand side. And on the right hand side, I have a function  $Px$  and this is the integration we can take. So from that one now and  $c$  is the **constant** of integration I am taking.

So from here why I am taking the modulus value because I am taking the logarithm and we know that log is defined for the positive functions, for the positive value. So this is the positive function. Now from here I want to find my  $y_x$ . So I take the logarithm, antilogarithm both side and then it becomes exponential  $- P(x) dx + c$ .

**(Refer Slide Time: 14:04)**

The image shows a handwritten derivation on a light-colored background. It starts with the equation  $|y(x)| = c e^{-\int p(x) dx}$ . The next line is  $\Rightarrow |y(x) - c e^{-\int p(x) dx}| = 0$  for all values of  $x$ . The third line is  $\Rightarrow y(x) - c e^{-\int p(x) dx} = 0$ . The fourth line is  $\Rightarrow y(x) = c e^{-\int p(x) dx} \quad \forall x$ . The fifth line is  $\Rightarrow \frac{dy}{dx} + p(x)y(x) = q(x)$  with a circled 6 next to it. The final line is  $\Rightarrow (Y)' = Q(X)$ .

So this one I can define as  $y_x$  modulus value is equal to  $e^{-\int P(x) dx}$ . So this is a minus value, minus, and this is the constant of integration I can multiply by  $c$ , this is a **new**  $c$ , okay. So from here I can write from this. Now, so this exponentially is **always** positive value. So from here I can write  $y_x$  and taking this on the left hand  $c e^{-\int P(x) dx}$  modulus value that is always equal to 1 in this case.

So this is true for all value of  $x$  and the function. So if the function is, the modulus of some function is equal to some constant for all value of  $x$ , then we know that then that function itself is a constant function. So from here I can define that this itself is 1 because for all value of  $x$ , the modulus value is equal to 1 and then we know that if it is happening then the function itself is equal to one.

So from here I can write that my  $y_x$  is equal to 1 no sorry. What happened? So from here I have taken this one from the right side. So this one. So this is equal to zero sorry, because I have taken on the left hand side. So from here I can write, so should I

erase this one. So this becomes 0 and this becomes 0. So from here, I can write this function as so  $yx$  can be written as  $c e^{px} dx$ .

So that is my solution. So this is true for all  $x$ . So this is the general solution for the corresponding homogeneous first order differential equation. So we are going to use this one, to solve little bit harder problem. Now so after **equipped with** the methods to solve a simpler forms. Now I am ready to solve the general form. So that general form I have written that  $dy/dx + P(x)y(x) = Q(x)$ .

So  $Q(x)$ , now as in the mathematics we know that whatever the knowledge we have gained till now we want to use that knowledge to solve the tougher problem. So in this case, we know that how to solve the differential equations, which has some simpler form. So we use that knowledge to solve this equation. So what we will do that. Now we will try to convert this equation into those form which are we are able to solve now till now.

So in this case, I want to make or I want to convert this differential equation into some of the form that some of the function, some of the functions  $F$  that I am able to solve  $Y$  dash is equal to some  $qx$ . So I want to convert this equation into this form and then we know that I can integrate this one and it will be the solution of that equation. So how do we can do that?

**(Refer Slide Time: 19:06)**

Multiply eq (1) with some function  $u(x)$

$$u(x) \frac{dy}{dx} + u(x) P(x)y = u(x) Q(x) \quad \text{--- } \textcircled{*}$$

$$\Rightarrow \frac{d}{dx} (u(x)y(x)) = u(x) Q(x)$$

$$\Rightarrow u(x) \frac{dy}{dx} + \frac{du}{dx} y(x) = u(x) Q(x) \quad \text{--- } \textcircled{*}$$

$$\Rightarrow \text{if } \frac{du}{dx} = u(x) P(x)$$

$$\Rightarrow u(x) = C e^{\int P(x) dx} \quad \boxed{C=1}$$

So now what I want to do, I multiply the equation the general equation, this equation I can write as, I can write as G. So this is the general equation I want to solve. So multiply equation G with some functions. So let us call it mu x, then we have mu x dy/dx + mu x P(x) y = mu x Q(x). So that is a function I am taking.

So I have multiplied this equation by the mu x such that, on the left hand side I should be getting a function which can be put in the form of a differentiation together. Now what I want is till now I am able to solve the differential equation. So I want to put this expression in this form that d/dx = (mu x y(x)) such that it should be equal to mu x Q(x). So this one I can take the derivative by the product rule.

So I can have this mu x dy/dx + d mu/dx yx. So that should be equal to mu x Q(x). So I want to reduce my equation in this form. So this is possible if I take that d mu/dx = mu x P(x) because if you compare this equation, this equation and this equation. So in this case, if I want to convert this one into this form then my d mu by dx should be equal to mu x Px.

And this is I know that I have already solved this equation and this equation has the solution mu x is equal to some constant and then e raised to power integration. So in this case P is there, so Px dx. So we are able to solve this form. Now for the simplicity I can take my c = 1.

(Refer Slide Time: 22:27)

The image shows a handwritten derivation of the integrating factor method for a linear differential equation. The steps are as follows:

$$\Rightarrow \mu(x) = e^{\int P(x) dx}$$

$$\Rightarrow e^{\int P(x) dx} \frac{dy}{dx} + e^{\int P(x) dx} P(x) y = e^{\int P(x) dx} Q(x)$$

$$\Rightarrow \left( e^{\int P(x) dx} y(x) \right)' = Q(x) e^{\int P(x) dx}$$

$$\Rightarrow e^{\int P(x) dx} y(x) = \int Q(x) e^{\int P(x) dx} + C$$

$$\Rightarrow y(x) = \frac{1}{e^{\int P(x) dx}} \left( \int Q(x) e^{\int P(x) dx} + C \right)$$

So from here I can write my  $\mu x$  is equal to  $e^{\int P(x) dx}$ . So I know the value of this  $\mu$  now. So if I have this value then by putting this value in the equation G so we have now  $P(x) dx$  it is  $dy/dx + P(x) dx$  into  $P(x) y = P(x) dx$  into  $Q(x)$  right? So on the left hand side we can write this equation as  $P(x) dx$  into  $y(x)$  whole derivate and that is equal to  $Q(x) e^{\int P(x) dx}$ .

So now this is the differential equation that we have a derivative on the left hand side and the **integrable function** on the right hand side. So we know that how to solve this one. We can integrate both side with respect to  $x$  and if I do the integration with respect to  $x$  both side then what I will get is  $e^{\int P(x) dx} y(x)$  becomes  $Q(x) e^{\int P(x) dx}$  plus some constant of integration and which further can be written as  $y(x)$  is equal to, so I can divide by this factor now.

So this factor if I take on the right hand side this becomes  $P(x) dx$  then  $Q(x) e^{\int P(x) dx}$  plus  $e^{-\int P(x) dx}$  into  $c$ . So we are able to solve this differential equation the general differential equation with the help of  $\mu$  function and that  $\mu$  is, this is my  $\mu$  function. So this  $\mu$  function has some special name.

**(Refer Slide Time: 25:11)**

$$\mu(x) = e^{\int P(x) dx}$$
 is called integrating factor.

Now Suppose, some initial condition is also given to us.

$$y(x_0) = y_0 \text{ (IVP)}$$

$$\left( \mu(x) y \right)' = Q(x) \mu(x) \text{ between } x_0 \text{ to } x$$

$$\left[ \mu(x) y \right]_{x_0}^x = \int_{x_0}^x Q(x) \mu(x) dx$$

So this  $\mu$  whatever we have written here, in this case  $P(x) dx$  is called integrating factor. So because it is helping us to make the differential equation the left hand side the differentiable. So this is the general solution for solving the general linear first order differential equation. Now, suppose some initial condition is also given.

So let us suppose I have a function  $y(x)$ , let us suppose I have a function  $y$  at  $x_0$  is equal to  $y_0$ . So this is my initial condition given to me. So I have the same general first order equation with this initial condition. So in this case my solution becomes now I, so I want just to let you know that how we can solve when the initial value is given to me.

So in this case I know that I already had the factor that is  $\mu(x)$  so  $\mu(x)$  is given to me. So I have  $\mu(x) y'(x) = Q(x) \mu(x)$ . So this is I have. Now I integrate both side with respect to  $x$  from  $x_0$  to  $x$  because I now starting with the point  $x_0$ . So between  $x_0$  to  $x$ . So in this case I have to integrate starting from the  $x_0$ . So integrate this one.

Then I will get  $\mu(x) y(x) - \mu(x_0) y_0 = \int_{x_0}^x \mu(s) Q(s) ds$ . So this is the definite integral we know.

**(Refer Slide Time: 28:06)**

$$\Rightarrow \mu(x) y(x) - \mu(x_0) y_0 = \int_{x_0}^x \mu(s) Q(s) ds$$

$$\Rightarrow y(x) = \frac{1}{\mu(x)} \left[ \mu(x_0) y_0 + \int_{x_0}^x \mu(s) Q(s) ds \right]$$

Ex-1  $\frac{dy}{dx} + 2x y(x) = x \quad y(1) = 2$  IVP

$p(x) = 2x$   
 $Q(x) = x$   
 $I.F = e^{\int 2x dx} = e^{x^2} = \mu(x)$

$\left( \frac{dy}{dx} + p(x)y(x) = Q(x) \right)$

So the left hand side now if we put the limit in that case, so it becomes  $\mu(x) y(x) - \mu(x_0) y_0$  and on the right hand side, I have factor  $\int_{x_0}^x \mu(s) Q(s) ds$ . So now I can change my internal variable, so I can write as  $\int_{x_0}^x \mu(s) Q(s) ds$  because now in this case, after putting the limit, I will get the function in  $x$ . So from here my solution becomes  $y(x) = \frac{1}{\mu(x)} \left( \mu(x_0) y_0 + \int_{x_0}^x \mu(s) Q(s) ds \right)$ .

Then  $\mu(x_0) y_0$  and  $y_0$  is given to me so why at  $x_0$  is given to me plus  $\int_{x_0}^x \mu(s) Q(s) ds$ . So this is my solution for the initial value problem. So

now we are able to solve any initial (value) problem, which has a general form of linear first order equation. So we are after developing this theory, just we want to solve some examples and we want to apply this theory that we are able to solve the differential equation or not. So now start with the example 1.

So let us I want to solve  $dy/dx + 2x yx = x$  with the initial condition that  $y_1 = 2$ . So this is my differential equation initial (value) problem, and it is starting with the point 1 and passing that  $y$  at  $x$  equal to 1 is equal to two. So now this is this differential equation is of the form  $dy/dx + P_x yx = Q_x$ . So in this case my  $P_x$  is  $2x$  and my  $Q_x$  is  $x$ .

And from here we can see that  $P_x$  is  $2x$  and  $Q_x$  is  $x$  and they are the continuous functions. So it is satisfying the condition based on that one. So from using this one I can define my integrating factor. So integrating factor is  $e$  into  $P_x$ ,  $P_x$  is  $2x dx$ . So it becomes  $e x$  square. So this is my integrating factor that is the  $\mu x$  we have defined in the last class, in the last slide.

**(Refer Slide Time: 31:37)**

The image shows handwritten mathematical work on a light-colored background. At the top, it says "Then,  $\mu(x) = e^{x^2}$ ". Below this, the general solution formula is written:  $y(x) = \frac{1}{\mu(x)} \left[ \mu(x_0) y_0 + \int_{x_0}^x \mu(x) Q(x) dx \right]$ . The next line shows the specific calculation for the integral:  $\int_1^x x e^{x^2} dx = \int_1^x s e^{s^2} ds = \frac{e^{x^2}}{2}$ . Finally, the general solution is boxed:  $y(x) = e^{-x^2} \left[ 2e + \frac{e^{x^2}}{2} \right]$ .

So once I have the integrating factor, then we know that I have the solution  $yx = 1/\mu x$  and then  $\mu x$  naught  $y$  naught plus. So in this case, my  $x$  naught is 1. So from 1 to  $x$  and then we have  $Q_x$  and the integrating factor  $\mu x dx$ . So this is my solution. So  $\mu x$  is I already know, that  $\mu x$  is  $e$  raised to power  $x$  square. So now this is already known, so I want to find out the right hand inside.

So this factor I want to find  $1$  to  $x$   $Qx$  is  $x$ . So  $e$  raised to power  $x$  square  $dx$ . So this one I want to find. So this can be also written as  $1$  to  $x$   $s$   $e$  raised to power  $s$  square  $ds$ . Now I know that this is a function and this is the derivative. So it can be written as  $e$  raised to power  $s$  square by  $2$ . So this will come  $e$   $x$  square, so this is written as  $e$   $x$  square by  $2$ . So this is my factor I have solved.

Now the general solution is  $yx$  is equal to, so  $\mu x$  is already known. So this becomes  $e$  raised to power minus  $x$  square and  $\mu$  at  $x$  naught, what is the  $\mu$  at  $x$  naught? What is  $x$  naught? So  $x$  naught is  $1$ . So  $\mu$  at  $x$  naught will be  $e$  only. So this will be  $e$  because putting just instead of  $x$ , I am putting  $x$  naught equal to  $1$ . So once I put the  $x$  equal to  $1$ , it becomes  $e$  and  $y$  naught is  $2$ .

So it becomes  $2$ , because in the previous you can see that this is  $y_1 = 2$ . So once I have  $y_1 = 2$  then this value becomes  $2e + e$   $x$  square by  $2$ . So after solving this equation, so this is my general solution for this initial value problem. So that is my solution. Now, so this is the example we have solved with the help of the our knowledge of solving the first order differential equation. So let us take some another example.

**(Refer Slide Time: 35:05)**

The image shows a handwritten derivation for the differential equation  $(x-a) \frac{dy}{dx} + 3y = 12(x-a)^3$  where  $x > a > 0$ . The steps are as follows:

$$\# \quad (x-a) \frac{dy}{dx} + 3y = 12(x-a)^3 \quad x > a > 0$$

$$\frac{dy}{dx} + \frac{3}{x-a} y = \frac{12(x-a)^3}{x-a} = 12(x-a)^2$$

$$P(x) = \frac{3}{x-a} \quad Q(x) = 12(x-a)^2$$

$$\Rightarrow \mu(x) = I.F. = e^{\int \frac{3}{x-a} dx} =$$

$(x - a) \frac{dy}{dx} + 3y = 12(x - a)$  power cube such that I have  $x$  is greater than  $a$  and greater than  $0$ . So this is given to me that  $x$  is greater than  $a$  and both are greater than  $0$ . So this differential equation is the first order linear differential equation and I want to solve this one. So in this case, first I want to put this one in the standard form. What

are the standard form we have? So in this case, I know that  $x$  is not equal to  $a$ , so I can divide by this factor.

**(Refer Slide Time: 35:52)**

Handwritten mathematical derivation on a whiteboard:

$$\# \quad (x-a) \frac{dy}{dx} + 3y = 12(x-a)^3 \quad x > a > 0$$

$$\frac{dy}{dx} + \frac{3}{x-a} y = \frac{12(x-a)^3}{x-a} = 12(x-a)^2$$

$$P(x) = \frac{3}{x-a} \quad Q(x) = 12(x-a)^2$$

$$\Rightarrow \mu(x) = \text{I.F.} = e^{\int \frac{3}{x-a} dx} =$$

So I can divide the whole equation with  $x - a$  and I will get  $3x - a y = 12x - a$  cube by  $x - a$ . So that will become  $12x - a$  power 2. So now in this equation we are able to convert into the standard form. So from here I know that my  $P_x$  is  $3/x - a$  and my  $Q_x$  is  $12x - a$  whole square. So this  $P_x$  and  $Q_x$  also continuous function because in this case  $x$  is never equal to  $a$ .

So this is also continuous function well defined function. Now in this case, to solve this one I apply the again the integrating factor. So I find out my  $\mu x$  that is the integrating factor. So this will be exponential  $P dx$ . So this is the integrating factor I want to solve. So if you solve this integrative factor, so it becomes

**(Refer Slide Time: 37:11)**

$$\begin{aligned}
 & \text{1) } \frac{dy}{dx} + 3y = 12(x-a)^3 \quad x > a > 0 \\
 & \frac{3}{x-a} y = 12 \frac{(x-a)^3}{x-a} = 12(x-a)^2 \\
 & Q(x) = 12(x-a)^2 \\
 & \text{I.F.} = e^{\int \frac{3}{x-a} dx} = e^{3 \ln(x-a)} = e^{\ln(x-a)^3} = (x-a)^3
 \end{aligned}$$

So  $e^3$  and  $x - a$  I can take, so this becomes  $\ln x - a$ . So that will become, because in this case my  $x - a$  is always positive because  $x$  is greater than  $a$ . So I have this value. This can be written as  $e^{\ln x - a}$  power cube and this is further can be written as  $x - a$  power cube. So now I have my integrating factor.

**(Refer Slide Time: 37:47)**

$$\begin{aligned}
 & (x-a) \frac{dy}{dx} + 3y = 12(x-a)^3 \quad x > a > 0 \\
 & \frac{dy}{dx} + \frac{3}{x-a} y = 12 \frac{(x-a)^3}{x-a} = 12(x-a)^2 \\
 & P(x) = \frac{3}{x-a} \quad Q(x) = 12(x-a)^2 \\
 & \mu(x) = \text{I.F.} = e^{\int \frac{3}{x-a} dx} = e^{3 \ln(x-a)} = e^{\ln(x-a)^3} \\
 & \text{I.F.} = (x-a)^3 \\
 & y(x) = \frac{1}{(x-a)^3} \left[ \int 12(x-a)^2 (x-a)^3 dx + C \right]
 \end{aligned}$$

So integrating factor in this case is  $x - a$  power **cube**. So that is my integrating factor. So the general solution  $yx$  can be written as  $1/x - a$  power  $q$  and then integrating with my  $Qx$  is 12. So it will be  $12 x - a$  square with the integrating factor  $x - a$   $Q dx + c$ . So that is the constant **of integration**. Because in this case, we do not have any initial condition. So this is a indefinite integrals.

**(Refer Slide Time: 38:54)**

$$y(x) = \frac{1}{(x-a)^3} \left( \int 12(x-a)^5 dx + C \right)$$

$$y(x) = \frac{1}{(x-a)^3} \left[ \frac{12(x-a)^6}{6} + C \right] = \frac{1}{(x-a)^3} [2(x-a)^6 + C]$$

First order Non-linear diff. eq.

① Bernoulli Equation:-

$$\frac{dy}{dx} + P(x)y(x) = Q(x)y^n \quad (n \in \mathbb{R})$$

Now if I solve this equation further, it can be written as my  $Yx$  becomes  $1/x$  – a power **cube** and this becomes  $12x - a$  power 5  $dx + c$ . So this is the solution and which can be further solved. So this is the power 6, So it becomes  $x - a$  power 6 by 6 into  $12 + c$ . So which can be further simplified and this equation becomes  $2x - a$  power 6  $+ c$  where  $c$  is the constant of integration.

So this is my general solution for this equation and  $c$  is the integration, the constant of integration. So using this one we are able to solve the first order, linear first order equation which have the standard form. Now I will also try to solve few nonlinear equations, which are very important and they are the first order equation. So I will just give you the example, because till now we have done only the linear equation which have the standard form.

Now I will give you some example, which has a nonlinear form. So first order nonlinear differential equation. So the most important is we start with the very important is first one is the Bernoulli equation. So Bernoulli equation we know. So Bernoulli equation is can be written as  $dy/dx + P(x)y(x) = Q(x)y$  raised to power  $n$  where the  $n$  belongs to real line. So this equation is looks similar to the standard form of the linear equation.

**(Refer Slide Time: 42:01)**

first order non-linear diff. eq.

① Bernoulli Equation:-

②  $-\frac{dy}{dx} + P(x)y(x) = Q(x)y^n \quad (n \in \mathbb{R})$

if  $n=0, 1$  ② is a linear.

Also for  $n > 0$ ,  $y=0$  is a sol. (trivial)

To find non-trivial sol

$u(x) = [y(x)]^{1-n}$

And now in this case if  $n$  is = zero, then it becomes just the simpler form of for  $n = 1$ , for  $n = 0$  and  $1$  the equation. So this is write as B. B means Bernoulli equation. This B is a linear. So linear form and that we can solve very easily. Now for also for ( $n$ ) greater than zero,  $y = 0$  is a solution. So that is a trivial solution because if you put  $n$  greater than zero  $y = 0$  is also one of the solution.

So for the non-trivial solutions now to find non-trivial solution, so what do we want? We want to convert this one into the form we are able to solve from the previous methods. So because this is the things we are doing then now this is a nonlinear equation. So by some transformation I want to transfer this equation into the known form which I have just solved. So further to find non-trivial solution.

So let us consider one transformation. So let I take a function  $u(x)$  is equal to some  $y(x)$ . So  $y(x)$  is the solution of this power  $1 - n$ . So this is a transformation I am taking.

**(Refer Slide Time: 44:07)**

$n > 0$  = linear diff. eq.  
Li Equation:-  
 $y' + P(x)y^n = Q(x)y^n \quad (n \in \mathbb{R})$   
 $n > 0, 1 \text{ (B) is a linear.}$   
 for  $n > 0, y > 0$  is a sol.  
 (Trivial)  
 $n < 0$  - trivial sol  
 $u(x) = [y(x)]^{1-n} \Rightarrow u'(x) = (1-n)[y(x)]^{-n} \frac{dy}{dx}$   
 $= (1-n)[y(x)]^{-n} y'(x)$

And using this transformation so from here, I can define that my u dash x it will be  $1 - n$  yx power, so  $1 - n - 1$  and that is  $dy/dx$ . So this is my derivative. So which can be further simplified and it becomes  $1 - n$  yx power  $-n$  and this is y dash. This is y dash x. Now which can be further solved, so this can be further solved.

**(Refer Slide Time: 45:00)**

$$\begin{aligned}
 u'(x) &= (1-n) y^{-n} [Q(x) y^n - P(x) y^n] \\
 &= (1-n) [Q(x) - P(x) y^{-n+1}] \quad u(x) = y^{-n} \\
 &= (1-n) [Q(x) - P(x) u(x)] \\
 \boxed{u'(x) + (1-n) P(x) u(x) &= (1-n) Q(x)} \\
 u(x) = I \cdot f &= \frac{(1-n) \int P(x) dx}{e} \\
 \boxed{u(x) \rightarrow y(x)}
 \end{aligned}$$

And we have you dash x becomes  $1 - n$  y raised to power  $-n$  and the y dash. So y dash I already know that my differential equation. So y dash can be written as  $qx y$  to power  $n - px yx$ . This is because I have just in the y dash I have put the form right hand inside. So which can be further simplified and if I take the Y minus raised to power minus  $(n)$  inside, so I will get  $qx - px y - n + 1$ . So this is I am getting.

So which can be further written as  $1 - n px - px$  and what is (this)  $y$ ? So I know that  $ux$  is  $y^{1-n}$ . So this is  $1 - n$ , so it becomes  $ux$ . So from here, I have my differential equation  $u \text{ dash } x$  is equal to, so this form I will take on the left hand side. So this one becomes plus  $1 - n px ux = 1 - n qx$ . So this is again the same form. So now this is my standard form, whatever the  $Px$  we have taken the previous and this is the capital  $Qx$  on the right hand side.

So this is the linear equation and I can solve this linear equation very easily and then by applying this one, so in this case my integrating factor because whenever I want to solve this type of linear equation, I need an integrating factor. So integrating factor in this case, that is my  $mu x$  will be  $e$  raised to power. So integrating factor in this case will be  $e$  raised to power  $1 - n px dx$ .

So once I know the integrating factor, I can solve this differential equation. And then once I know the value of the solution  $ux$ , so because this is a linear equation  $ux$ , so from here I will get the value of  $ux$ . So once I know the value of  $ux$  from here I can find the value of  $yx$  by just putting back into the transformation. So let us do one example that how to solve a Bernoulli equation. So let us take one example. So let us take.

**(Refer Slide Time: 48:07)**

Solve  $\frac{dy}{dx} + xy = xy^2$  ( $n=2$ )

Let  $u(x) = [y(x)]^{1-n} = [y(x)]^{-2} = \frac{1}{y(x)}$

$u'(x) = -\frac{1}{y^2} \frac{dy}{dx} = -\frac{1}{y^2} [xy^2 - xy]$

$\frac{du}{dx} = -x + \frac{x}{y}$

$\Rightarrow \frac{du}{dx} = -x + xu(x)$

$\frac{du}{dx} - xu(x) = -x$

$p(x) = -x$   
 $Q(x) = -x$

So let us solve the differential equation  $dy/dx + xy = xy$  square. So this is a nonlinear equation because nonlinear because we have  $y$  square on the right hand side and this is a Bernoulli equation for  $n = 2$ . So now I want to solve this differential equation. So

I will take the same transformation. So let my  $u = y^2$  so I define  $u$ ,  $u$  is  $= y^2$  power 1 -  $n$ . So in this case my  $n$  is equal to 2. So that becomes  $y^2 - 2$ . So it is  $1/y^2$ .

So this is my transformation  $u$ . And in this case my  $u'$  will be  $-2/y^3 dy/dx$ . And  $dy/dx$  is already given to me. So from here I will get, so  $dy/dx$  can be written as  $xy^2 - x/y$ . Now I take the factor inside, so I will get  $-x$  and  $+x/y$ . So I have a differential equation of this type now. So this differential equation can be written as again I will, so minus further I have  $du/dx = -x$ .

Now what I have taken,  $u = 1/y^2$ . So from here I can write, so this can be written as  $x u'$ . So this is the equation I want to solve. So from here which can be solved, so this equation can be further written as  $du/dx - x u = -x$ . So this is again in the form of  $P(x)u + Q(x) = R(x)$ . So in this case my  $P(x)$  is  $-x$  and my  $Q(x)$  is also  $-x$ . So if I solve this differential equation further then

**(Refer Slide Time: 51:36)**

$$u(x) = 1 + C e^{x^2/2}$$

$$I.F = e^{\int -x dx} = e^{-x^2/2}$$

$$y(x) = \frac{1}{u(x)} = \frac{1}{1 + C e^{x^2/2}}$$
Ex 
$$x \frac{dy}{dx} + y = \frac{1}{y^2} \Rightarrow \frac{dy}{dx} + \frac{y}{x} = \frac{1}{x^2}$$

$$u(x) = [y(x)]^{-2} = [y(x)]^{-2} = y^{-2}$$

$$\Rightarrow u'(x) = \frac{3}{x} - \frac{3}{x} u(x) \Rightarrow u'(x) + \frac{3}{x} u(x) = \frac{3}{x}$$

So if I solve this one, I will get the solution. So this you can solve yourself, then I will get the solution  $u = 1 + c e^{\text{raised to power } x^2 \text{ by two}}$ , because integrating factor in this case is  $e^{-x^2}$ . So that becomes  $e^{\text{raised to power } -x^2 \text{ by 2}}$ . So this is my integrating factor. So this is a solution in the terms of  $u$  and if I take the solution in the  $y$ , so  $y$  can be written as  $y$  is  $1/u$ .

So this will be  $1 + c e^{\text{raised to power } x^2 \text{ by 2}}$ . So that is the solution of this Bernoulli equation. So by the transformations, we are able to convert or transform in

(a) nonlinear differential equation into the linear differential equation and the linear differential equation we know how to solve that differential equation. So we can take another example of the Bernoulli form and that we take  $x \frac{dy}{dx} + y = 1/y^2$ .

So in this case this is a Bernoulli form for  $n = -2$ . But first I will transform this one into the standard form. So here we take that  $x$  is never equal to 0. I convert this one into divide by  $x$ . So I can write this as  $y/x + 1/xy^2$  and which can be written as  $y^{-2}/x$ . So this is the again the binomial Bernoulli form with my  $n = -2$ . Now this is also a nonlinear equation and this is in the Bernoulli form. So I want to solve this equation.

Now the criteria is same. I will take the transformation, transform this nonlinear equation to the first total linear equation and then I will solve with the help of integrating factor. So in this case the transformation let I have my  $u$  and that is the  $y^{1-n}$ . So in this case my  $y^{-2}$  becomes  $u$ . So it will becomes  $u$ . So that is my transformation. So you square is equal to  $y^3$ .

So if I apply the same transformation, I will get my differential equation. So differential equation this case becomes  $u \frac{dx}{dx} = 3/x - 3/x u$ . So this is a differential equation we are getting which can be further solved and which can be written as  $u \frac{dx}{dx} + 3/x u = 3/x$ . So this is my linear first order differential equation of the form of the standard form, which can be further solved and if I solve further, you can solve this equation by yourself.

**(Refer Slide Time: 55:43)**

$$u(x) = 1 + \frac{c}{x^3}$$
$$y(x) = [u(x)]^{1/3} = \left(1 + \frac{c}{x^3}\right)^{1/3}$$

And in this case, I will get the solution  $ux = 1 + c x^{\text{cube}}$ . So this is the solution I got. So by the transformation I know that my  $y_x = u_x$  power  $1/3$ . So my  $y_x$  solution becomes  $1 + c$  over  $x^{\text{cube}}$  power  $1/3$ . So that is the general solution for the given Bernoulli form. So we are able to solve the very famous Bernoulli equation, which is highly nonlinear by taking the [transformation](#) and converting that one into the linear form.

So in the today lecture, we have discussed that how to solve the linear differential equation and then we have extended to the Bernoulli equation which is highly nonlinear by taking the [transformation](#) we are able to convert the Bernoulli equation into the linear equation and which can be solved with the help of integrating factor.

So thanks very much for listening me and from the next class we will go further and solve the Riccati equation and some important classification like separable equations and exact differential equation. Thank you very much.
