Lecture - 9
Multiple Linear Regression (Contd.)

Hi, this is 4th lecture on multiple linear regression, and know the last lecture we have considered one example on Multiple Linear Regression, there the model multiple linear regression model has been fitted. And the significance and the usefulness of the multiple linear regression model has been a tested using the global test, and also using the partial test, we have the tested, the significance of say for example, X_1 in the presence of X_2 . Basically, the test statistic, we have used there is t statistic, well so this can be done also using the extra sum of square technique. So, I am going to talk you know, about how to test the significance of one regressor variable, in the presence of other regressor variable, using extra sum of squares technique well.

(Refer Slide Time: 02:23)

Well, so this one is you know, this one is usually used, to test for several parameters being 0, but here I am using this technique to test simple hypothesis like $H_0: \beta_2 = 0$, against the alternative hypothesis $H_1: \beta_2 \neq 0$. So, this one, we can be I mean, we already we have tested this hypothesis, using the t

statistic, but now we will be using you know extra sum of square technique to test this hypothesis.

Well so this hypothesis can also be written as you know H_0 non hypothesis Y equal to $\beta_0 + \beta_1 X_1 + \epsilon$ against the alternative hypothesis, that is Y equal to $\beta_0 + \beta_1 X_1 + \beta_2 X_2 + \epsilon$. So, whether it is enough to consider, this model or it is necessary to consider the full model, so this is basically the full model and the non hypothesis says that, it is to go for the restricted model well.

So, what we do in the extra sum of square technique is that, we compute $SS_{\text{regression}}$ both for the model like, for first we compute the $SS_{\text{regression}}$ for the full model and also, we compute the value of the $SS_{\text{regression}}$ for the restricted model. So, here is the restricted model, so what is the $SS_{\text{regression}}$ value, when there is only one regressor, in the model and what is the $SS_{\text{regression}}$ value, when there are 2 regressor variables in the model.

(Refer Slide Time: 05:52)

Handwritten calculations on a blue background:

$$SS_{\text{Res}} = \sum_{i=1}^{11} e_i^2 = 68$$

$$SS_T = \sum (Y_i - \bar{Y})^2 = \sum Y_i^2 - n\bar{Y}^2 = 289 - 11 \times 9 = 190$$

$$SS_{\text{Reg}} = SS_T - SS_{\text{Res}} = 190 - 68 = 122$$

ANOVA TABLE Full model

Source of variation	DF	SS	MS	F
Regression	2	$SS_{\text{Reg}} = 122$	61	7.17
Residual	8	$SS_{\text{Res}} = 68$	8.5	
Total	10	190		

So, for these 2 values I will recall my previous class, you know this one is my ANOVA table in my previous class, for the full model, this one is for the full model, please refer my last class. So, here the $SS_{\text{regression}}$ value is a 122 and the SS_{residual} value is 68, so I will copy these 2 values, $SS_{\text{regression}}$ is equal to 122 and also you know, SS_{residual} for the full model is equal to 68.

(Refer Slide Time: 06:47)

Pr. How useful is the regression using X_1 alone?

X_1	Y	\hat{Y}	e
1	6	8.135	-2.135
4	8	6.059	2.946
...
6	5		

$Y = 9.162 - 1.027 X_1$

$SS_{Res} = \sum_{i=1}^n e_i^2 = 79$, $SS_T = 196$, $SS_{Reg} = 116$

ANOVA TABLE $Y = \beta_0 + \beta_1 X_1 + \epsilon$

Source of Variation	DF	SS	MS	F
Regression	1	116	116	14.15
Residual	9	79	8.2	
Total	10	196		$F_{0.05, 1, 9} = 5.12$

Now, I will refer my previous lecture, for the restricted model, so here is the restricted model, I mean we have fitted this model, using only one regressor and here is the ANOVA table for my restricted model, that model here is called to is beta, Y equal to beta naught plus beta 1 X 1 plus epsilon and here is the S S regression 116 well.

(Refer Slide Time: 07:27)

Extra Sum of Squares Method

$H_0: \beta_2 = 0$ ag. $H_0: Y = \beta_0 + \beta_1 X_1 + \epsilon$ ag.
 $H_1: \beta_2 \neq 0$ $H_1: Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \epsilon$

$SS_{Reg}^{Full} = 122$ $SS_{Reg}^{Restricted} = 116$

$SS_{Res}^{Full} = 68$ $SS_{Reg}^{Full} - SS_{Reg}^{Restricted} = 6$

$t = -0.83$ $F = \frac{(SS_{Reg}^{Full} - SS_{Reg}^{Restricted}) / 1}{SS_{Res}^{Full} / 8} = \frac{6}{8.5} = .7$

$t^2 \approx F$ $F = .7 < F_{0.05, 1, 8} = 5.32 \sim F_{1, 8}$

H_0 is accepted

So, S S regression for the restricted model is equal to 116, now the difference you know, we know that S S regression increases as the number of regressor variables increases. So, this is the S S regressor for the full model and this is the S S regression, for the restricted

model, now the difference $SS_{\text{regression}}$ minus for the full model and $SS_{\text{regression}}$ for the restricted model is equal to 6.

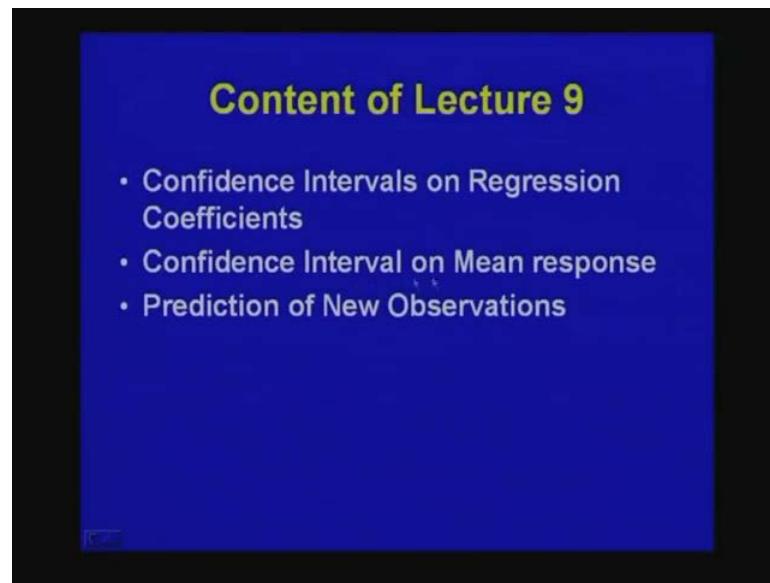

So, this one is you know, this one is called the extra sum of square, due to β_2 or you can say that, this is the extra sum of square, some of square means, it is extra the regression sum of square, due to the regressor X_2 . Because, this one this $SS_{\text{regression}}$ is involving both X_1 and X_2 and this $SS_{\text{regression}}$ is involving only X_1 , so the difference is the $SS_{\text{regression}}$, due to X_2 . Now, the F statistic for this extra sum of square technique is you know, $SS_{\text{regression}}$ for the full model minus $SS_{\text{regression}}$ for the restricted model by the degree of freedom.

Here the degree of freedom of this one is only one, because here β_2 is not a affecter, it is just only one regression coefficient and it is corresponds to X_2 , so F is this by SS_{residual} for the full model by the degree of freedom. The degree of freedom is equal to 8, if you can you can refer my previous class, well so this is equal to 6 by this is nothing but MS_{residual} , which is equal to 8.5, which is equal to 0.7 and we know that this, if statistic follows F distribution with degree of freedom 1 and 8.

So, what we do is that, we compare the observed value of F , which is equal to 0.7 with the tabulated value $F_{0.05, 1, 8}$, the value of this one is 5.32. So, the observed value is less than the tabulated value; that means, the conclusion is that, the hypothesis H_0 is accepted. So, the meaning of this one is that, you know that, we accept the hypothesis that $\beta_2 = 0$, the meaning of this one is the regressor variable X_2 is not significant, in the presence of X_1 in the model.

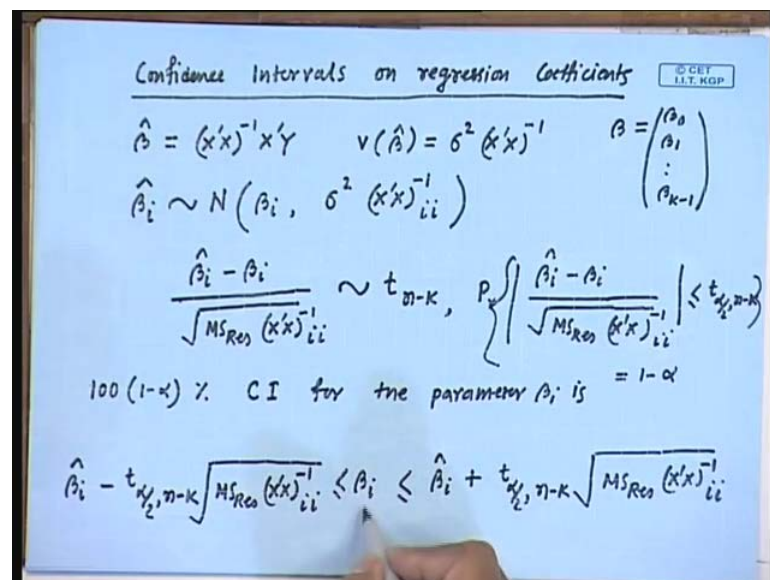

So, basically we got the same result, I mean we concluded the same thing in using that t test also, so this is another way to you know, this is another way to do the same testing, this is you know using the extra sum of square technique well. Also just I want to mentioned here is that the, if you use the t statistic then the t statistic value is equal to minus 0.83. So, here you can check that, t^2 value is equal to is almost, you know same equal to F and this is you know in general, this is true. So, whether you go, for the t test or you use the extra sum of square method, to test this hypothesis, you will be getting the same result, well next basically the content of today's lecture is you know will be talking about, confidence interval on regression coefficients.

(Refer Slide Time: 13:27)

Also the confidence interval on mean response and ones the model has been fitted you know, it is very important you know, one important issue is to predict prediction of new observation, for a given value of regressor variable well.

(Refer Slide Time: 13:59)

So, next we talk about, confidence intervals on regression coefficients, so here the regression coefficient is beta, which is vector beta naught beta 1 up to beta K minus 1 right. And you want to find you know the confidence interval for beta i for any i well, what we know is that to find the confidence interval, first you need to have the point

estimator of beta, we know that, $\hat{\beta}$ is equal to $(X'X)^{-1}X'Y$, this is an unbiased estimator of beta.

So, basically this one is $\hat{\beta}_i$ is a point estimator and also, we know that, the variance of $\hat{\beta}_i$ is equal to $\sigma^2(X'X)^{-1}_{ii}$, now from here, we can say that $\hat{\beta}_i$ follows normal distribution with mean β_i and the variance $\sigma^2(X'X)^{-1}_{ii}$. So, this one is you know, this notation, we have used several time, this is the i th element in $(X'X)^{-1}$.

Now, from here, I can write $\frac{\hat{\beta}_i - \beta_i}{\sqrt{\sigma^2(X'X)^{-1}_{ii}}}$, I am replacing this σ^2 by MSE , this random variable follows t distribution with degree of freedom $n - K$, because we have $K - 1$ regressor well. Then obviously, you know, we can say that, $\frac{\hat{\beta}_i - \beta_i}{\sqrt{MSE(X'X)^{-1}_{ii}}}$ the absolute value of this one is less than or equal to $t_{\alpha/2, n-K}$, this has probability equal to $1 - \alpha$.

So, if you choose you know $\alpha = 0.05$, this random variable is a absolute value, this random variable is less than $t_{\alpha/2, n-K}$ is 0.95. So, from here, we get 100 into $1 - \alpha$ percent confidence interval for the parameter β_i is you know, you can get β_i is in between $\hat{\beta}_i \pm t_{\alpha/2, n-K} \sqrt{MSE(X'X)^{-1}_{ii}}$ and similarly the lower bound is $\hat{\beta}_i - t_{\alpha/2, n-K} \sqrt{MSE(X'X)^{-1}_{ii}}$. So, this is the 95 percent confidence interval for the i th regressor point α is equal to 0.05, similarly you can get similar confidence interval, for the other regressor coefficient from for the other coefficient also.

(Refer Slide Time: 20:12)

Confidence interval on Mean Response at a particular point, say $x_0 = (1, x_{01}, x_{02}, \dots, x_{0, k-1})$

$$E(Y|x_0) = x_0 \beta$$

An unbiased estimator of $E(Y|x_0)$ is $\hat{y}_0 = x_0 \hat{\beta}$

$$E(x_0 \hat{\beta}) = x_0 E(\hat{\beta}) = x_0 \beta.$$

$$V(\hat{y}_0) = V(x_0 \hat{\beta}) = x_0 V(\hat{\beta}) x_0'$$

$$= x_0 \sigma^2 (X'X)^{-1} x_0'$$

$$\frac{\hat{y}_0 - x_0 \beta}{\sqrt{x_0 M_{Res} (X'X)^{-1} x_0'}} \sim t_{n-k}$$

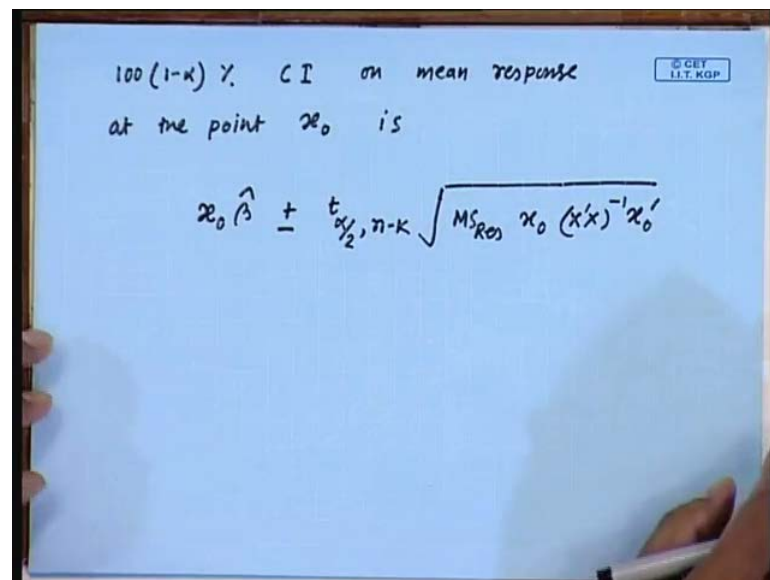

So, next will be talking about, confidence interval, on mean response at a particular point say x naught is equal to 1, x naught 1, x naught 2, x naught K minus 1 well, so what we want is that, we want the expected response value at this point. So, these are the this is the value of first regressor, second regressor and the K th regressor, so at this point, we are looking for the expected response value, so what we want to estimate first is that, we want to estimate the expected, so if you need we looking for the confidence interval for this expected value or mean response at the point x naught.

So, the usual technique, you know to find the confidence interval for this one, first you have to look for the point estimation of this one well, what is this quantity, this quantity is nothing but or this is nothing but x naught beta, so x naught is a 1 cross K vector and beta is a K cross 1 vector right. Well we know that an unbiased estimator of this expected response at the point X naught is for the unbiased estimator of this one is nothing but X naught beta hat is X naught beta hat and we call it say y hat y naught hat.

So, this one is an unbiased estimator of this quantity, because beta hat is an unbiased estimator of beta, so you can prove that, you know expected value of x naught beta hat is equal to x naught expectation of beta hat, which is equal to x naught beta. And the variance of next, we compute the variance of the unbiased estimator y naught hat, which is equal to the variance of x naught beta hat right. Now, this variance is equal to x naught the variance of beta hat into x naught prime well.

So, this one is nothing but we know the variance of beta hat is equal to sigma square x prime x, x inverse x naught prime well, so from here, I can say see my unbiased estimator y naught hat has expectation this and variance this. So, I can say that, y naught hat minus x naught beta, you know this by x naught M S residual, I am just replacing sigma square by M S residual x prime x inverse x naught prime, this quantity for this random variable, it follows t distribution with degree of freedom n minus K right. So, from here you know using this, I can give now 100 into 1 minus alpha percent confidence interval for the expected response, this is the expected response. So, i can get the confidence interval for this expected response now.

(Refer Slide Time: 26:33)

100(1- α)% C I on mean response
at the point x_0 is

$$x_0 \hat{\beta} \pm t_{\alpha/2, n-k} \sqrt{MS_{Res} x_0 (X'X)^{-1} x_0'}$$

So, therefore, you know hundred into 1 minus alpha percent confidence interval on mean response at the point x naught is x naught beta hat, which is nothing but y naught hat plus t alpha by 2 n minus K into M S residual x naught X prime X inverse x naught prime. So, this is the upper bound of the interval and the lower bound is obtained by just replacing the plus sign by the by minus, so this one is basically, the confidence interval for the expected response at the point x equal to x naught well.

(Refer Slide Time: 28:10)

prediction of new observations

© CEY
I.I.T. KGP

$$E(Y|x_0) = x_0\beta$$

$$x_0 y_0 = x_0\beta + \varepsilon$$

$$x_0 = (1, x_{01}, \dots, x_{0, k-1})$$

A point estimator of the future observation y_0 at the point x_0 is $\hat{y}_0 = x_0\hat{\beta}$

$$\psi = \hat{y}_0 - y_0, \quad E(\psi) = 0$$

$$V(\psi) = V(\hat{y}_0 - y_0) = \sigma^2(1 + x_0(x'x)^{-1}x_0')$$

$$\frac{\hat{y}_0 - y_0}{\sqrt{MS_{Res}(1 + x_0(x'x)^{-1}x_0')}} \sim t_{n-k}$$

So, next we will be talking about, a prediction of new observation, well so this is a very important aspect, because you know, once you have the fitted model that, fitted model, if it is a significant 1 then that model can be used the regressor model can be to predict new observations, corresponds to particular value of the response variance well. So, here what you want is that, we want to predict the value new observation at the point at say x naught equal to 1 x naught 1 x naught K minus 1 well.

So, this one is bit for simple linear regression also, we had the same sort of problem, the difference between the expected response and the new observation at the point x naught is you know expected response at the point x naught is nothing but x naught beta. But, the observation here, what we looking for is that you know, we are trying to predict the future observation, y naught at the point x equal to x naught, I mean when x naught means, it is for the given values of the regressor variable well.

So, here we are trying to estimate y naught, this y naught is according to the model, this y naught is nothing but x naught beta plus epsilon, so in the previous case, we try to estimate this expected response and here, we are trying to predict the value of this one difference. But, the starting point will be same will start with the point estimation or point estimator of this one, so a point estimator of the future observation y naught at the point x naught is again, we call it y naught hat, which is equal to x naught beta hat.

Well so you see the difference here, you know you are starting with the same point estimator, so this point estimator, we have used to estimate the expected response well, but now, this point estimator is not an unbiased estimator of this thing, but because we have the excellent term here. So, that is why, we define new random variable χ , which is equal to \hat{y} , the same strategy has the simple linear regression model, \hat{y} minus y and the expected value of this random variable is equal to 0.

This is not difficult to check, because expectation of these is equal to 0 and the variance of this one, you can check that variance of this one is variance of χ is equal to the variance of \hat{y} minus y , which is equal to $\sigma^2 (1 + x' (X'X)^{-1} x)$. Let me explain see the first term is σ^2 , which is basically the variance of y and the second term is the variance of \hat{y} , you know why it is.

So, and these 2 are independent, because this is a new observation and this \hat{y} , you know it consist of the previous observations the given observations y_1, y_2, \dots, y_n and this one is an independent observation future observation right. So, from here, we can say that, \hat{y} minus y by $MSE (1 + x' (X'X)^{-1} x)$, so I just replace σ^2 by MSE . So, this random variable follows t distribution with degree of freedom $n - K$ right and from here from the distribution of this random variable, we can get the prediction interval, we call it prediction, the same thing confidence interval or prediction interval for \hat{y} .

(Refer Slide Time: 35:15)

Thus $100(1-\alpha)\%$ P.I for y_0 is

$$x_0 \hat{\beta} \pm t_{\alpha/2, n-k} * \sqrt{MS_{Res} (1 + x_0 (x'x)^{-1} x_0')}$$

So, thus $100(1-\alpha)\%$ prediction interval, for y_0 is equal to $x_0 \hat{\beta}$, this is nothing but y_0 hat, this is nothing but y_0 hat plus minus $t_{\alpha/2, n-k}$ into $MS_{Res} (1 + x_0 (x'x)^{-1} x_0')$. Well so this is how we get the prediction interval, for future observation, now just give one example to illustrate, this confidence interval or prediction interval, let me consider the same example.

(Refer Slide Time: 36:39)

Example

The variance of the predicted value of Y for the point $x_1 = 3, x_2 = 5$

x_1, x_2, Y $x_0 = (1, x_{01}, x_{02}) = (1, 3, 5)$

point estimator of Y $\hat{y}_0 = x_0 \hat{\beta}$

$V(\hat{y}_0) = x_0 \sigma^2 (x'x)^{-1} x_0'$ $MS_{Res} = 8.5$

$= 8.5 (1, 3, 5) \begin{pmatrix} 9.37 & -0.849 & -0.4086 \\ 0.169 & 0.0822 & 0.0422 \end{pmatrix} \begin{pmatrix} 1 \\ 3 \\ 5 \end{pmatrix}$

$= 1.95$

As in my last class and here I want to consider the problem that, you know, you find the variance of the predicted value of Y , for the point x_1 equal to 3 and x_2 equal to 5. So, if you can recall my last example, there we had 2 regressors x_1 x_2 and Y , now what this problem says you that know, you find the variance of predicted value of y for when x_1 equal to 3 and x_2 equal to 5, so here my x naught is what I said x naught is you know, $1 \ x \text{ naught } 1 \ x \text{ naught } 2$, so this one is nothing but $1 \ 3 \ 5$, this is my x naught right.

Now, what is the point estimation of estimator of y , the point estimator of y call it y naught hat, which is nothing but x naught beta hat and what we want here is that, we want variance of this point estimator. So, the variance of y naught hat is equal to x naught the variance of beta hat, which is equal to $\sigma^2 X' X^{-1} x$ naught prime right. Now, to estimate you know, we cannot compute the variance, because σ^2 is not known, so you have to replace this σ^2 by $M S$ residual, so σ^2 is equal to 8.5, because $M S$ residual value is equal to 8.5.

Now, my x naught is you know, this is a scalar quantities, now my x naught is $1 \ 3 \ 5$ and you know that $x' x$ is $x' x^{-1}$, which is equal to 4.37 minus 0.849 please refer my last lecture, minus $0.4086 \ 0.16 \ 9.082 \ 2.0422$ into $1 \ 3 \ 5$. May just I am giving this example, so that you know, just to illustrate just to illustrate, whatever the theory, I just explain. And from here, you know it is not now not difficult to check that, this is you know this is 1×3 , this one is 3×3 and 3×1 , so ultimately a value of this one is going to be 1.95.

So, this is the estimated variance of the predicted value of Y at this point you know, once you have this variance, you can find the confidence interval or prediction interval very easily. So, that is all regarding the confidence interval or prediction interval in multiple linear regression, next I have some time, so I want to solve one problem from simple linear regression, this will I hope this will help you, to understand, you know more on one degree of freedom, how to calculate the degree of freedom. So, constitute this problem from the simple linear regression.

(Refer Slide Time: 42:23)

problem SLR
Consider the simple linear regression model
$$y = \beta_0 + \beta_1 x + \varepsilon$$

where β_0 is known
a. Find LSE of β_1 for this model.
Fitted model $\hat{y} = \beta_0 + \hat{\beta}_1 x$
$$e_i = y_i - \hat{y}_i = (y_i - \beta_0 - \hat{\beta}_1 x_i)$$

$$SS_{Res} = \sum_1^n e_i^2 = \sum (y_i - \beta_0 - \hat{\beta}_1 x_i)^2$$

$$\frac{dSS_{Res}}{d\hat{\beta}_1} = 0 \Rightarrow \sum (y_i - \beta_0 - \hat{\beta}_1 x_i) x_i = 0$$

$$\hat{\beta}_1 = \frac{\sum (y_i - \beta_0) x_i}{\sum x_i^2}$$

In the simple linear regression, well so the model is y equal to β_0 plus $\beta_1 x$ plus ε as usual, here we say that β_0 is known, so this is the only difference. So, you really you know do not need to estimate β_0 , because you know β_0 value is given, so only thing you need to do is that you know, you need to estimate the value of the slope, that is you know β_1 . So, the first problem, it says that find list of square estimator of β_1 , for this model well you know.

So, you need to understand that opposite that, you know to estimate word to find the list square estimator of β_1 , you need to I mean that will be obtained by minimizing the SS_{Res} . So, you assume that the fitted model is you know, y equal to β_0 plus $\beta_1 \hat{x}$ plus it is x , so suppose your fitted model is \hat{y} , which is equal to β_0 plus $\beta_1 \hat{x}$. So, I am not putting see, I did not put $\beta_1 \hat{x}$ because, β_0 is known well.

So, my e_i is equal to y_i minus \hat{y}_i , so here it is y_i minus β_0 minus $\beta_1 \hat{x}_i$, this is my i th residual, now SS_{Res} residual sum of square, which is equal to some e_i^2 from 1 to n , this is going to be $(y_i - \beta_0 - \beta_1 \hat{x}_i)^2$ well. So, the list square estimate of β_1 can be obtained by minimizing the SS_{Res} and here, you have only one unknown parameter, so you just differentiate SS_{Res} with the respect to $\hat{\beta}_1$ and this equal to 0 will give you the normal equation.

So, the normal equation is $y_i - \beta_0 + \beta_1 x_i$, which is basically e_i into x_i equal to 0, so here you will get only one normal equation, because there is only one unknown parameter and solving this normal equation, we will get the estimator of β_1 hat. So, from here, we get β_1 hat is equal to summation $y_i - \beta_0 x_i$ by summation x_i^2 . So, this is the least square estimator of β_1 hat, so I mean, what I want to say is that you know, you here you do not need to differentiate with respect to β_0 , because β_0 is known, so you do not need to estimate that.

(Refer Slide Time: 48:00)

b. Find $100(1-\alpha)\%$ CI for β_1 .

$$\hat{\beta}_1 = \frac{\sum (y_i - \beta_0) x_i}{\sum x_i^2} \quad y_i = \beta_0 + \beta_1 x_i + \epsilon$$

$$E(\hat{\beta}_1) = E\left(\frac{\sum (\beta_1 x_i + \epsilon_i) x_i}{\sum x_i^2}\right) = \frac{\beta_1 \sum x_i^2}{\sum x_i^2} = \beta_1$$

$$V(\hat{\beta}_1) = \frac{\sigma^2}{\sum x_i^2} \quad \frac{\hat{\beta}_1 - \beta_1}{\sqrt{\frac{MS_{Res}}{\sum x_i^2}}} \sim t_{n-1}$$

$100(1-\alpha)\%$ CI for β_1 is

$$\hat{\beta}_1 \pm t_{\alpha/2, n-1} \sqrt{\frac{MS_{Res}}{\sum x_i^2}}$$

So, the next problem no find problem b, it says find hundred into 1 minus alpha confidence interval for β_1 hat, so to find this one, we need to confidence interval for β_1 , it is not β_1 hat find 100 into 1 minus alpha percent confidence interval for β_1 . So, you know that an unbiased, we do not know whether it, so will start from the least square estimator of β_1 that is β_1 hat, which is equal to summation $y_i - \beta_0 x_i$ by summation x_i^2 .

Well so this is a point estimator of β_1 , now will check, what is the expected value of this β_1 hat, β_1 hat is equal to you put, what is y_i , y_i is equal to $\beta_0 + \beta_1 x_i + \epsilon_i$. So, if you put this will be replaced by $\beta_0 + \beta_1 x_i + \epsilon_i$ into x_i by summation x_i^2 and the expected value of this one, so here you can check

that you know, the second term is 0, because expected value ϵ_i is equal to 0. So, this is going to be β_1 into summation x_i^2 by summation x_i^2 .

So, it is an unbiased estimator of β_1 and also you can check that the variance of $\hat{\beta}_1$ is equal to σ^2 by summation x_i^2 right. So, from these 2, I can write you know, $\hat{\beta}_1 - \beta_1$ by if I replaced this σ^2 by MSE residual by MSE residual some over x_i^2 is this follows t distribution with degree of freedom, so the here is the here, I want to discuss little bit it is degree of freedom $n - 1$.

Because there are degree of freedom of SSE residual is $n - 1$ by SSE residual is summation e_i^2 i equal to 1 to n and you have the freedom of choosing $n - 1$ e_i and the last one the n th one e_n has to be choose an in such a way, there is such that, it satisfy the constant that $e_i x_i$ equal to 0. So, here you have to note that, you know there is only one constant on e_i .

So, that is why you are losing, the degree of freedom by 1 and thus the degree of freedom residual is equal to $n - 1$, it is not $n - 2$, in case of you know usual for the simple linear regression model, when both β_0 and β_1 are unknown the degree of freedom, for this one is $n - 2$. Here since β_0 is known, we are defined setting with the respect to only β_1 and we get one normal equation, which is nothing but $e_i x_i$ equal to 0. So, there is only one constrain on residuals. So, that is why the degree of freedom is $n - 1$. So, now, I can write 100 into $1 - \alpha$ percent confidence interval, for β_1 is $\hat{\beta}_1$, I write just plus minus $t_{\alpha/2, n-1}$, MSE residual by summation x_i^2 . So, that is all for today.

Thank you very much.
