Lecture - 22
Multivariate Analysis VII

In the previous class we have discussed methods for testing of parameters for 1 multivariate normal distribution and also for 2 multivariate normal distributions. So for example if we have 1 sample from normal μ σ distribution of p dimension then we can test about $\mu = \mu_0$. We have seen that if σ is known then the test will be based on a chi square statistic whereas if σ is unknown then the test is based on Hotelling's T square statistics.

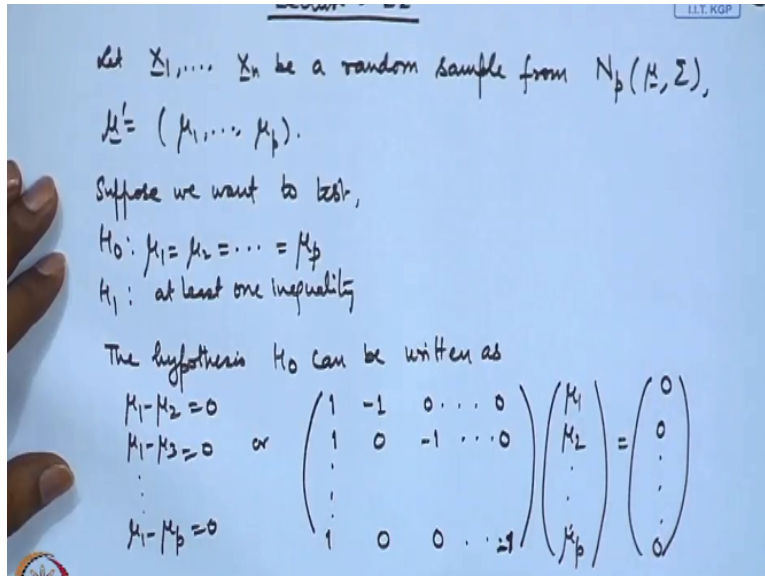

And we have shown equivalence that the value of the T square statistics can be calculated from an F distribution and the corresponding formula was given. We also discussed 2 sample problem that means we can consider testing for the equality of the mean vector of 2 multivariate normal population $\mu_1 = \mu_2$ and again if the co-variance matrices were known the test was based on a chi square.

As well they were unknown, but equal then it was based on a Hotelling's T square distribution. One more application of this type of testing I also showed for the linear functions of mean vector that we can consider the test for that. Now another application of this is that we may consider equality of the components themselves. Now this could be like this that.

For example, this μ_1, μ_2, μ_p they may be denoting the characteristics of say different components of something which may have similarities. So now we would like to know whether the $\mu_1 = \mu_2 = \mu_p$ or not that is something like a test for homogeneity. Now we know that in analysis of variance we have a test when we are considering several normal populations then it is called a one-way analysis of variance test.

But there the populations are considered to be independent that means the sampling procedure that means we are having then p independent samples. Now here by definition the samples are not independent because it is coming from a multivariate normal population.

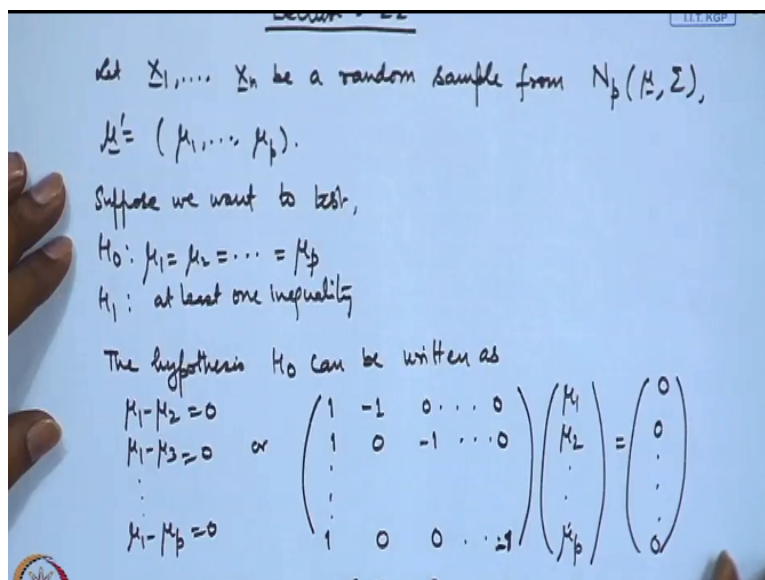

(Refer Side Time: 02:30)

So now I present a procedure for this. Let us consider a random sample x_1, x_2, \dots, x_n be a random sample from $N_p(\mu, \Sigma)$. So as usual μ vector let me write it in the row form then $\mu^T = \mu_1, \mu_2, \dots, \mu_p$. Now suppose we want to test say $H_0: \mu_1 = \mu_2 = \dots = \mu_p$ against at least one inequality. So what we do we write it like this.

We can consider the hypothesis H_0 can be written as $\mu_1 - \mu_2 = 0, \mu_1 - \mu_3 = 0$ this is $= 0$ and so on $\mu_1 - \mu_p = 0$ which we can write as say $1, -1, 0, 0, 0, 1, -1, 0$ and so on $1, 0, 0, \dots, -1, \mu_1, \mu_2, \dots, \mu_p$ this is $= 0, 0, 0$.

(Refer Slide Time: 04:48)

This is we can consider it as some C matrix multiplied by $\mu = \text{null}$ where C is actually $(p-1) \times p$ matrix. Now you see this statement which is written in a linear form like $\mu_1 = \mu_2 = \dots = \mu_p$. I can consider it as $(p-1)$ simultaneous linear functions of the μ vector of the components of

μ . So we can write it as $C\mu=0$.

(Refer Slide Time: 05:36)

So we are equivalently testing

$H_0: C\mu = 0$

$H_1: C\mu \neq 0$

Consider $Y_j = CX_j \sim N_{p-1}(C\mu, C\Sigma C')$
 $j=1, \dots, n.$

Define $\bar{y} = \frac{1}{n} \sum_{i=1}^n Y_i$, $S_y = \frac{1}{n-1} \sum_{j=1}^n (Y_j - \bar{y})(Y_j - \bar{y})'$

$= \frac{1}{n} C \sum X_i$ $= \frac{1}{n-1} C \sum (X_j - \bar{x})(X_j - \bar{x})' C'$

$= \frac{1}{n} C \bar{x}$ $= \frac{1}{n-1} C S_x C'$

So we are equivalently testing $H_0, C\mu=0$ against H_1 say $C\mu$ is not $= 0$. So consider the transformation say $Y=CX$. So this will become then $p-1/1$ vector then this will follow N_{p-1} , $C\mu$ and C sigma C transpose. So let us consider y_j vectors or $j= 1$ to n and define then y bar vector as the mean vector of y_i and we can also define the variance covariance metrics based on y as $1/n-1$ sigma y_j-y bar y_j-y bar prime $j=1$ to n .

In fact, is nothing but see this one for example it is $=1/n C$ times sigma X_i and similarly this one is $1/n-1 C$ times sigma $x_j- x$ bar, x_j-x bar prime C prime that is actually $1/n-1 CSC$ prime where this S is based on x .

(Refer Slide Time: 07:28)

Define $\bar{y} = \frac{1}{n} \sum_{i=1}^n Y_i$, $S_y = \frac{1}{n-1} \sum_{j=1}^n (Y_j - \bar{y})(Y_j - \bar{y})'$

$= \frac{1}{n} C \sum X_i$ $= \frac{1}{n-1} C \sum (X_j - \bar{x})(X_j - \bar{x})' C'$

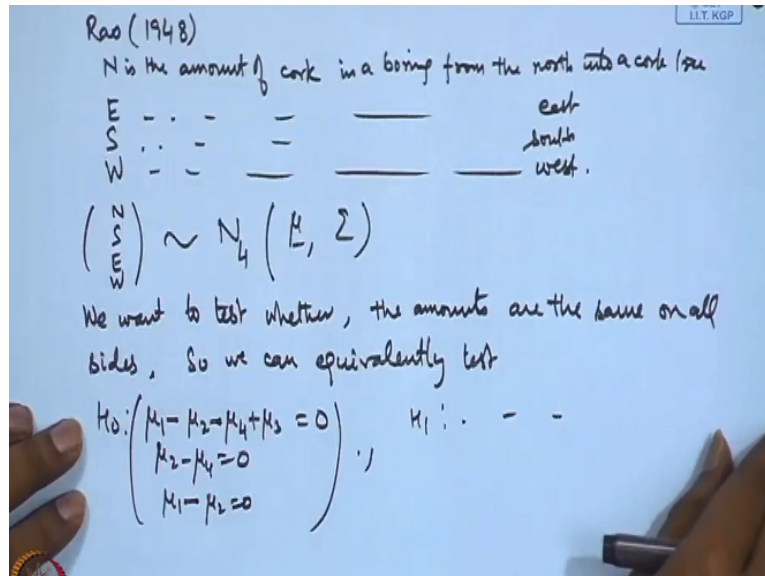

$= \frac{1}{n} C \bar{x}$ $= \frac{1}{n-1} C S_x C'$

We can use the test statistic

$T_y^2 = n \bar{y}' S_y^{-1} \bar{y}$, this will have $T_{(p-1), n-1}^2$

And this is simply so we can make use of the test statistic. Let us call it T^2 that is $\bar{y}' S^{-1} \bar{y}$. This will have T^2 distribution on $p-1$, $n-1$ this is $p-1$ dimensional here and of course $n-1$ because you have n observations here.

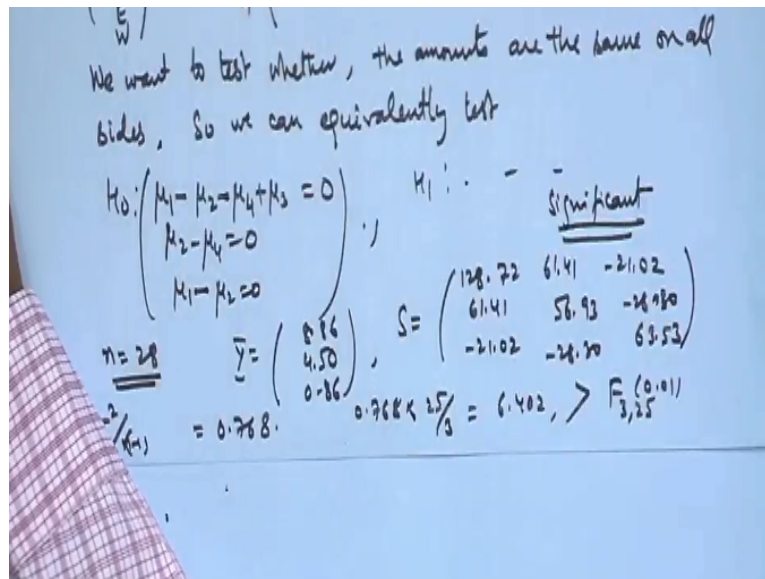

(Refer Slide Time: 08:17)

Let me give one example which is adopted from C. R Rao 1948 work and here N is the amount of I have used the terminology of that only which is amount of the cork in a boring from the north into a cork tree. And similarly you can consider E , S , W this is from East, this is from South and W is from the West and it is considered that $NSEW$ this follows a 4 dimensional multivariate normal distribution with some mean vector μ and variance covariance matrix σ .

And we want to test whether the amounts are the same on all sides. So we can write so as I have explained here we can use this set of hypothesis $\mu_1 - \mu_2 = 0$, $\mu_1 - \mu_3 = 0$, $\mu_1 - \mu_4 = 0$ or we can also use say $\mu_1 - \mu_2 - \mu_4 + \mu_3 = 0$, $\mu_2 - \mu_4 = 0$, $\mu_1 - \mu_2 = 0$ etcetera. So we can write it in any other fashion and against H_1 some inequality here.

(Refer Slide Time: 10:49)

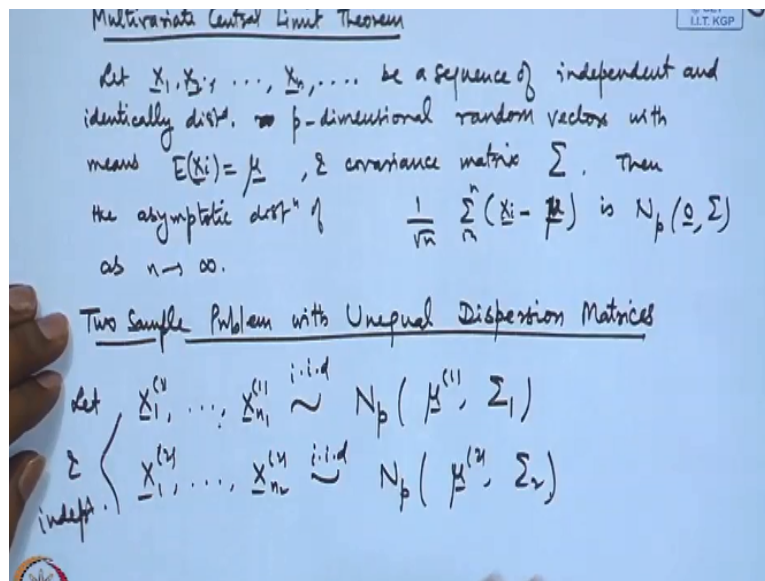

So the experiment that was conducted and reported in Rao it was having 28 observations based on that \bar{y} was found to be 8.86, 4.50 and 0.86 and S was calculated 128.72, 61.41-21.02, 61.41-21.02, 56.93-28.30, -28.30, 63.53. So if we calculate the T square value here $n-1$ that turns out to be 0.768. And if I consider compared to the F here then multiplied by $25/3$ that is 6.402 and if I consider F value on 325 say at 0.01 then this is more than this.

So this turns out that this is significant. That means the amounts which are collected from all the 4 sides they vary. So this is an application of Hotelling's T square we can basically what we are showing here is that we can consider linear functions here. Now as in the case of 1 variable the importance of the normal distribution (()) (12:24) from the fact that if we consider the sums of the observation from a sample or the means of the observation from the sample then using central limit theorem we get the approximate normal distribution.

Now a similar result holds for the multivariate data also.

(Refer Slide Time: 12:48)

So we can call it Multivariate Central Limit Theorem. So that is one reason that why the methods for the multivariate normal distributions are widely applicable. So we had in the following form that let x_1, x_2, X_n and so on be a sequence of independent and identically distributed p dimension random vectors with means as μ and covariance metric say σ . Then the asymptotic distribution of say $1/\sqrt{n} \sum_{i=1}^n (X_i - \mu)$ is $N_p(0, \Sigma)$ as $n \rightarrow \infty$.

This is $N_p(0, \Sigma)$ as n tends to infinity. So this is a version of that I have not considered divisions that means in the case of univariate we were considering σ here, but that we are not putting here because you have a matrix here. So at the most you can consider multiplication by σ to the power $-1/2$ here but that is of course easy to understand. So this type of result is helpful to establish that we can actually use the 1 sample and 2 samples procedures that we have discussed here for the multivariate normal distribution.

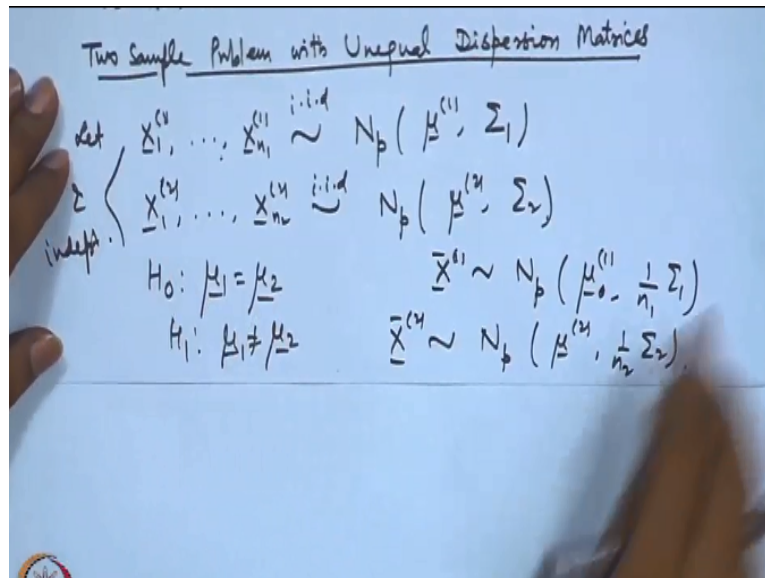

They will be widely applicable. Now one more case that for which in the univariate case we had some approximate procedure that was when we are considering the test for equality of variance means, but the variances are unknown as well as we do not have any other information on them like they are equal then we have a procedure which is the pooled procedure and for which I have presented the analog for the multivariate case also for the pooled Hotelling's T square.

But when they are not equal then in the case of one variable we had some approximate procedures. Now in the case of multivariate we present some procedure which is based on considering a curtailment of the observations. So let me present one procedure here. So two

sample problem with unequal dispersion matrices. So we consider let x_{11} let us go back to the notation that I introduced earlier x_{11}, n_1 here.

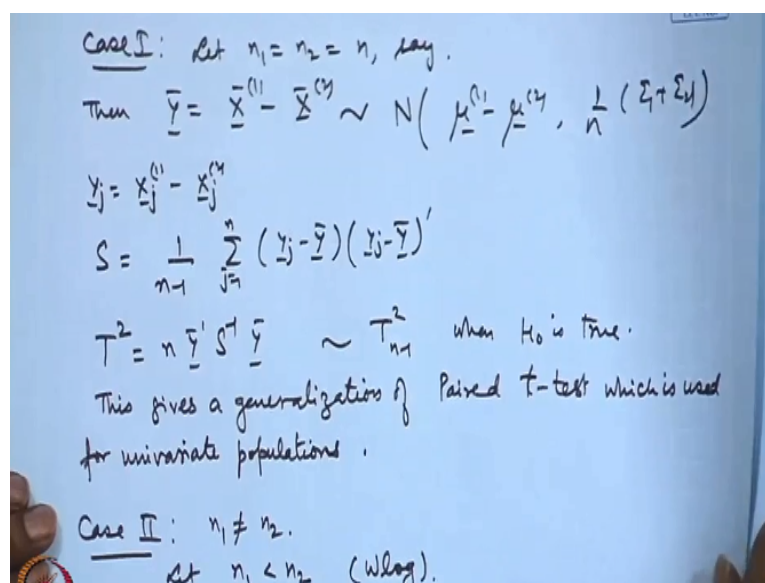

This is $N_p(\mu_1, \Sigma_1)$ and another random sample say x_{12} and so on x_{n_2} this is random sample from $N_p(\mu_2, \Sigma_2)$. So we have 2 independent random samples and these 2 samples are also considered to be independent here.

(Refer Slide Time: 17:00)

We are considering the test of hypothesis $\mu_1 = \mu_2$ against $\mu_1 \neq \mu_2$. Let me write the summary statistics here for example if I consider the mean. The first mean that will be $N_p(\mu_1, 1/n_1 \Sigma_1)$ and the second mean which I call X_2 that will be $N_p(\mu_2, 1/n_2 \Sigma_2)$.

(Refer Slide Time: 17:39)

So if I consider let $n_1 = n_2 = n$. Then if I considered y bar that is X bar 1 - X bar 2 then that will

be normal $\mu_1 - \mu_2, 1/n \sigma_1 + \sigma_2$. You can see here that this because of this coefficient getting $1/n_1$ and $1/n_2$ being same I can combine this $\sigma_1 + \sigma_2$. And therefore I can consider here say $y_j = x_{1j} - x_{2j}$. Based on this we can define $S = 1/(n-1) \sum (y_j - \bar{y})^2$.

And we can consider Hotelling's T-square $\bar{y} \prime S^{-1} \bar{y}$. So this will follow T square on $n-1$ when H_0 is true. So this gives a generalization of paired t test. The paired t test that we defined in the case of univariate populations which is used for univariate populations. Now let us consider the second case which is the more important one that is $n_1 \neq n_2$. So if $n_1 \neq n_2$ without loss of generality let us consider that $n_1 < n_2$.

(Refer Slide Time: 19:58)

$$Y_j = \frac{X_j^{(1)}}{\sqrt{n_1}} - \sqrt{\frac{n_1}{n_2}} \frac{X_j^{(2)}}{\sqrt{n_2}} + \frac{1}{\sqrt{n_1 n_2}} \sum_{k=1}^{n_1} X_k^{(2)} - \frac{1}{n_2} \sum_{r=1}^{n_2} X_r^{(2)}$$

$$E(Y_j) = \frac{\mu_1}{\sqrt{n_1}} - \sqrt{\frac{n_1}{n_2}} \frac{\mu_2}{\sqrt{n_2}} + \frac{n_1}{\sqrt{n_1 n_2}} \frac{\mu_2}{n_1} - \frac{n_2}{n_2} \mu_2$$

$$= \frac{\mu_1}{\sqrt{n_1}} - \mu_2$$

The covariance matrix between Y_A & Y_B is

$$E \left[\begin{matrix} Y_A - E Y_A \\ Y_B - E Y_B \end{matrix} \right] \begin{matrix} \\ \end{matrix}$$

$$= E \left[\begin{matrix} \left(\frac{X_1^{(1)}}{\sqrt{n_1}} - \mu_1 \right) - \sqrt{\frac{n_1}{n_2}} \left(\frac{X_1^{(2)}}{\sqrt{n_2}} - \mu_2 \right) \\ \left(\frac{X_2^{(1)}}{\sqrt{n_1}} - \mu_1 \right) - \sqrt{\frac{n_1}{n_2}} \left(\frac{X_2^{(2)}}{\sqrt{n_2}} - \mu_2 \right) \\ \vdots \\ \left(\frac{X_{n_1}^{(1)}}{\sqrt{n_1}} - \mu_1 \right) - \sqrt{\frac{n_1}{n_2}} \left(\frac{X_{n_1}^{(2)}}{\sqrt{n_2}} - \mu_2 \right) \end{matrix} \right] \begin{matrix} \\ \\ \vdots \\ \end{matrix}$$

In this case let us define say y_j that is $x_{1j} - \sqrt{n_1/n_2} x_{2j} + 1/\sqrt{n_1 n_2} \sum_{k=1}^{n_1} x_{k2} - 1/n_2 \sum_{r=1}^{n_2} x_{r2}$. You see here that in what way we have defined see this is the observations from the first sample and here the observation from the second sample are considered here. This definition we are considering from 1 to n_1 . So the remaining observation that we are putting together here. Let us see the effect here.

If I consider the mean of this, then I get here the mean of the first one that is $\mu_1 - \sqrt{n_1/n_2} \mu_2$ the mean of the second one that is $\mu_2 +$ now here the mean of x_{k2} is μ_2 and these are n_1 observations so it becomes $n_1/\sqrt{n_1 n_2} \mu_2$ and here it will become $n_2/n_2 \mu_2$. You look at this terms here this term will simply get cancelled out. So we are actually getting $\mu_1 - \mu_2$.

That means if we base our test on the mean of y_j then it will be able to test about equality of μ_1 and μ_2 . Also let us consider the covariance matrix between say 2 observations say y_α and y_β that is $\text{expectation of } y_\alpha y_\beta - \text{expectation } y_\alpha \text{ expectation } y_\beta \text{ transpose}$. So this we expand this is $\frac{1}{n_1} \sum_{\alpha=1}^{n_1} y_\alpha y_\beta - \frac{1}{n_1} \sum_{\alpha=1}^{n_1} y_\alpha \frac{1}{n_2} \sum_{\beta=1}^{n_2} y_\beta$. So this is $\frac{1}{n_1} \sum_{\alpha=1}^{n_1} (y_\alpha - \bar{y}) (y_\beta - \bar{y})'$.

This is from $r=1$ to n_2 * this transpose. Now if we consider this if I consider this into the first term here then that will give me simply the first one that is σ_1 the variance covariance matrix of x_α and let us adjust the terms for the other one also.

(Refer Slide Time: 23:31)

$$\begin{aligned}
 &= \delta_{\alpha\beta} \Sigma_1 + \frac{n_1}{n_2} \delta_{\alpha\beta} \Sigma_2 \\
 &+ \Sigma_2 \left(-\frac{2}{n_2} + \frac{n_1}{n_1 n_2} - \frac{2n_1}{\sqrt{n_1 n_2} n_2} + \frac{n_2}{n_2} + \frac{2}{n_2} \sqrt{\frac{n_1}{n_2}} \right) \\
 &= \delta_{\alpha\beta} \left(\Sigma_1 + \frac{n_1}{n_2} \Sigma_2 \right)
 \end{aligned}$$

Thus a suitable statistic for testing $H_0: \mu_1 = \mu_2$ is

$$T = n_1 \bar{y}' S^{-1} \bar{y} \quad \left(T_{n_1-1}^2 \quad \bar{y} = \frac{1}{n_1} \sum_{j=1}^{n_1} y_j \right)$$

$$(n_1-1) S = \sum_{\alpha=1}^{n_1} (y_\alpha - \bar{y})(y_\alpha - \bar{y})'$$

$$\bar{y} = \frac{1}{n_1} \sum_{\alpha=1}^{n_1} y_\alpha$$

$$U_\alpha = y_\alpha - \sqrt{\frac{n_1}{n_2}} \bar{y}$$

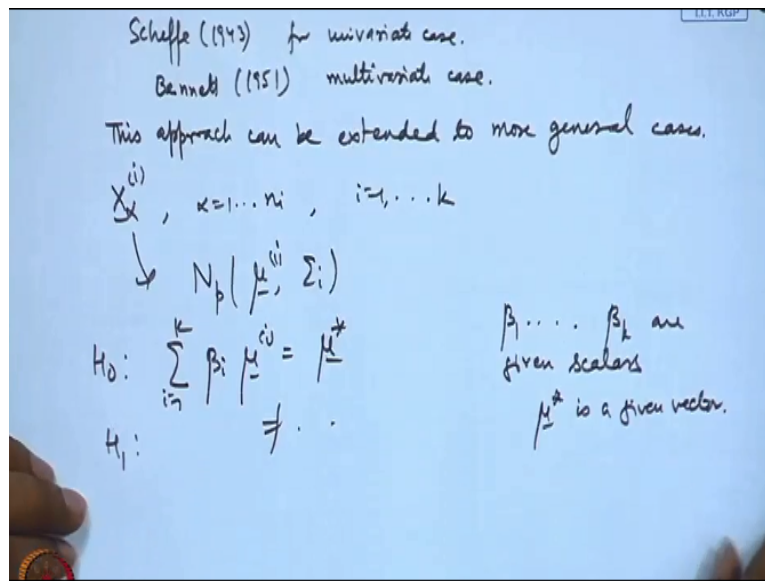

$$= \sum (U_\alpha - \bar{U})(U_\alpha - \bar{U})'$$

So this gives us that is this coefficient we combine together delta, alpha, beta. See this delta, alpha, beta will be 1 when $\alpha=\beta$ otherwise it is 0 $\sigma_1 + n_1/n_2 \delta_{\alpha\beta} \sigma_2 + \sigma_2 \left(-\frac{2}{n_2} + \frac{n_1}{n_1 n_2} - \frac{2n_1}{\sqrt{n_1 n_2} n_2} + \frac{n_2}{n_2} + \frac{2}{n_2} \sqrt{\frac{n_1}{n_2}} \right)$. So after simplification I get simply $\delta_{\alpha\beta} \left(\sigma_1 + \frac{n_1}{n_2} \sigma_2 \right)$. So based on this I can easily define suitable statistic for testing $\mu_1 = \mu_2$.

It is based on so $n_1 \bar{y}' S^{-1} \bar{y}$ this will have T^2 on n_1-1 where \bar{y} is nothing, but $\frac{1}{n_1} \sum_{j=1}^{n_1} y_j$ and $n_1-1 S$ that is nothing but $y_\alpha y_\alpha'$ transpose $\alpha=1$ to n_1 . Again this can be simplified if I substitute the terms here that is if I write the full form of this y_α and \bar{y} here then this is actually giving us $\sum U_\alpha U_\alpha'$ where $U_\alpha = y_\alpha - \sqrt{\frac{n_1}{n_2}} \bar{y}$.

And U_α are nothing, but $x_\alpha - \sqrt{\frac{n_1}{n_2}} x_\alpha$. This is for $\alpha=1$ to n_1 .

(Refer Slide Time: 26:24)

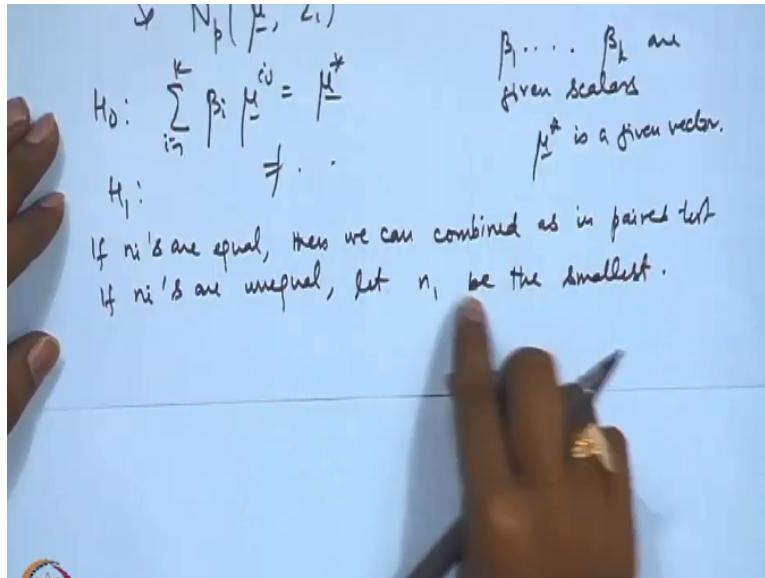

So this procedure was proposed by Scheffé in 1943 for the univariate case and Scheffé actually showed that this gives us the shortest confidence interval for the T distribution using the T distribution. Here we are actually making sacrifice of some of the observations and Bennett in 1951 he gave an extension to the multivariate case. Now one can actually consider it for several populations also when we are considering the linear combinations.

So what you will have to do you have to consider the minimum sample size of all the observations and based on that you can construct the statistics. Let me just demonstrate that thing here. This approach can be extended to more general cases. Let us consider say $X_{\alpha}^{(i)}$ or $\alpha=1$ to n_i $i=1$ to k . So these are samples are N_p say μ_i Σ_i . So we are considering k independent samples from k N_p μ_i Σ_i population.

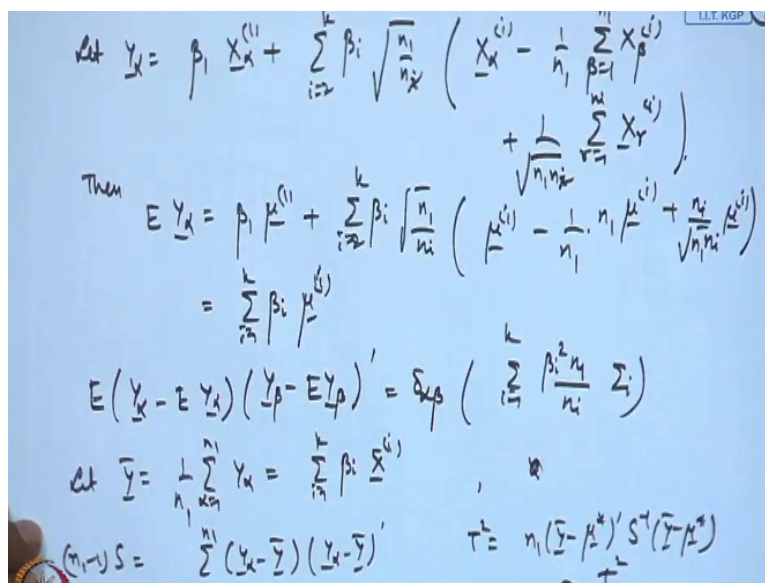

And we are considering testing for a linear combination of the mean vectors against say not equal where this $\beta_1, \beta_2, \beta_k$ are given scalars and this μ^* is given vector.

(Refer Slide Time: 28:39)

If n_i 's are equal, then there is no problem then we can combine as in paired test. If n_i 's are unequal, let n_1 be the smallest and like in the previous one we consider based on n_1 . So again here we will do it on base of n_1 .

(Refer Slide Time: 29:14)

And we can define y_α to be $\beta_1 x_\alpha + \sum_{i=2}^k \beta_i \sqrt{\frac{n_1}{n_i}} \left(x_\alpha - \frac{1}{n_i} \sum_{p=1}^{n_i} x_p^{(i)} + \frac{1}{\sqrt{n_1 n_i}} \sum_{r=1}^{n_1} x_r^{(i)} \right)$. This is from 2 to k and now we adjust the terms $x_\alpha - \frac{1}{n_i} \sum_{p=1}^{n_i} x_p^{(i)} + \frac{1}{\sqrt{n_1 n_i}} \sum_{r=1}^{n_1} x_r^{(i)}$ to $x_\alpha - \frac{1}{n_1} \sum_{r=1}^{n_1} x_r^{(i)}$. Then if we consider say expectation of y_α then it is simply becoming $\beta_1 \mu_1 + \sum_{i=2}^k \beta_i \mu_i$ from first term here $+ \sum_{i=2}^k \beta_i \sqrt{\frac{n_1}{n_i}} \left(\mu^{(i)} - \frac{1}{n_i} n_i \mu^{(i)} + \frac{n_i}{\sqrt{n_1 n_i}} \mu^{(i)} \right)$ this should be $n_1 \mu_i$ here $n_1 n_i$ and μ_i .

So this term gets cancelled out n_1/n_i this gets cancelled here. So you get simply $\beta_i \mu_i$ which is the desired term in the hypothesis here. So we can consider and similarly if we

consider the variance covariance matrix of this based on y alpha y beta-expectation y beta transpose then that is $= \sigma \beta_i \bar{x}_i$ where of course \bar{x}_i is the mean of the (i) (31:46) sample. And $n_1 - S$ is y alpha $-y$ bar y alpha $-y$ bar transpose alpha $= 1$ to n_1 . Then if I consider t square as $n_1 y$ bar $-\mu$ * prime S inverse y bar $-\mu$ * then that will have t square p $n_1 - 1$. So we can consider the Hotelling's T square test based on this here.

And so this is $= \sigma \beta_i \bar{x}_i$ where of course \bar{x}_i is the mean of the (i) (31:46) sample. And $n_1 - S$ is y alpha $-y$ bar y alpha $-y$ bar transpose alpha $= 1$ to n_1 . Then if I consider t square as $n_1 y$ bar $-\mu$ * prime S inverse y bar $-\mu$ * then that will have t square p $n_1 - 1$. So we can consider the Hotelling's T square test based on this here.

(Refer Slide Time: 32:27)

If we define $u_\alpha = \sum_{i=1}^k \beta_i \sqrt{\frac{n_1}{n_i}} X_\alpha^{(i)}$, $\alpha = 1, \dots, n_1$
 Then $S = \sum_{\alpha=1}^{n_1} (u_\alpha - \bar{u}) (u_\alpha - \bar{u})'$
 $X = \begin{pmatrix} X^{(1)} \\ \vdots \\ X^{(i)} \end{pmatrix}$, $\mu = \begin{pmatrix} \mu^{(1)} \\ \vdots \\ \mu^{(i)} \end{pmatrix}$
 $\Sigma = \begin{pmatrix} \Sigma_{11} & \vdots & \Sigma_{12} \\ \vdots & \ddots & \vdots \\ \Sigma_{21} & \vdots & \Sigma_{22} \end{pmatrix}$

If I define say u alpha $= \sigma \beta_i \sqrt{n_1/n_i} X$ alpha $i=1$ to k for alpha $= 1$ to n_1 then based on this S is nothing, but $\sigma \sum u$ alpha $-u$ bar u alpha $-u$ bar transpose. So one can use this based on the Hotelling's T square statistics. Another problem which may also arise that I consider the 2 sub vectors of the full vector and now I want to test whether they are having equal components that means like first one I write as $\mu_1 \mu_2$ second as μ_3, μ_4 then whether $\mu_1 = \mu_3, \mu_2 = \mu_4$ etcetera.

So this type of problem can also be handled using the Hotelling's T square. Let me give one example. Suppose I consider x_1 and x_2 here and $\mu =$ say μ_1, μ_2 . So these are partitioned here, these are partitioned here and similarly the variance covariance matrix is partitioned.

(Refer Slide Time: 34:10)

$$\underline{X} = \begin{pmatrix} \underline{X}^{(1)} \\ \vdots \\ \underline{X}^{(q)} \end{pmatrix} \quad \underline{\mu} = \begin{pmatrix} \underline{\mu}^{(1)} \\ \vdots \\ \underline{\mu}^{(q)} \end{pmatrix}$$

$$\underline{\Sigma} = \begin{pmatrix} \Sigma_{11} & \Sigma_{12} \\ \Sigma_{21} & \Sigma_{22} \end{pmatrix} \quad \Sigma^* = \Sigma_{11} - \Sigma_{12} - \Sigma_{12} + \Sigma_{22}$$

$$\underline{X}^{(1)} - \underline{X}^{(2)} \sim N_q(\underline{\mu}^{(1)} - \underline{\mu}^{(2)}, \Sigma^*)$$

So we are assuming here this as q components this as q components okay. So if I consider say $\bar{x}_1 - \bar{x}_2$ then that will have q dimensional normal distribution with mean $\mu_1 - \mu_2$ and variance covariance matrix Σ^* where this Σ^* can be then written as $\Sigma_{11} - \Sigma_{21} - \Sigma_{12} + \Sigma_{22}$.

(Refer Slide Time: 34:48)

If we want to test $H_0: \underline{\mu}^{(1)} = \underline{\mu}^{(2)}$, $H_1: \underline{\mu}^{(1)} \neq \underline{\mu}^{(2)}$, then we can consider the statistic

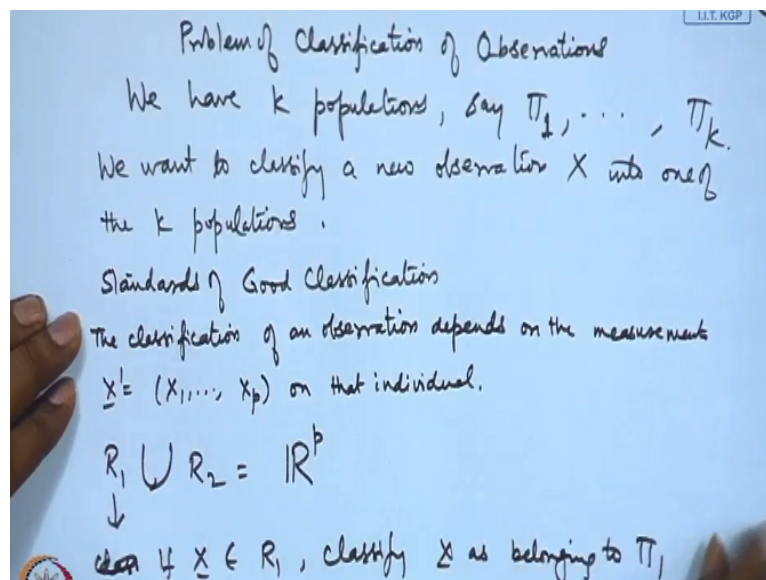

$$n (\bar{\underline{X}}^{(1)} - \bar{\underline{X}}^{(2)}) (S_{11} - S_{21} - S_{12} + S_{22})^{-1} (\bar{\underline{X}}^{(1)} - \bar{\underline{X}}^{(2)})'$$

T^2
 $\sim T^2_{q, n-1}$

So if we want to test say $H_0 \mu_1 = \mu_2$ against say $H_1, \mu_1 \neq \mu_2$. So we can consider the statistics $n \bar{x}_1 - \bar{x}_2 S_{11} - S_{21} - S_{12} + S_{22}$ inverse $\bar{x}_1 - \bar{x}_2$ transpose. So this will be based on Hotelling's T square on $n-1$ $q-1$ here sorry q and $n-1$ here. I have shown that various inferential problems for the mean vectors of 1 or 2 multivariate normal populations or several multivariate normal population or they can be handled using the Hotelling's T square statistics.

So there are other things which are based on the variance covariance you have something based on the Wishart distribution. However, I am not discussing that part right now because the testing for the variance covariance matrix will be somewhat little more complicated rather we move over to a more practical oriented problem which is called a Problem of Classification.

(Refer Slide Time: 36:42)

Let me introduce this problem here Problem of Classification of Observations. So quite frequently we are encountered with various kind of problem for example you consider a new entrant for example college. Now the students of the college can be described into 2 parts. One who go for an academic career and another who go for corporate job. Now based on the previous data we have the distribution of the 2 student performances.

Now when new student is considered then to which group he would belong to. Now this kind of problem can be considered in a more general setting. We have k population say $\pi_1, \pi_2, \dots, \pi_k$. We want to classify a new observation X into one of the k populations. So broadly speaking this is the problem of classification. Now here there can be several variations for example we may know the forms of $\pi_1, \pi_2, \dots, \pi_k$.

For example, this could be normal say μ_1, σ_1 , normal μ_2, σ_2 normal μ_k, σ_k and now we have another vector say x new observable we want to classify where it will belong to. Here it could be that $\mu_1, \sigma_1, \mu_2, \sigma_2, \mu_k, \sigma_k$ are known. There could be another problem when these parameters are unknown in that case we need some sort of observations from each of the populations.

Because then we will need to estimate $\mu_1, \mu_2, \dots, \mu_k$ and $\sigma_1, \sigma_2, \dots, \sigma_k$. These are called training samples. There can be yet another type of problem when the forms of $\pi_1, \pi_2, \dots, \pi_k$ are completely unknown. So in that case we have non parametric procedures. So let me introduce this problem that means what are the procedures and in what way we can study this.

So what are the standards of good classification? In a very rough way simple way we can say if we classify an observation into one of the population then either it is a correct classification or it is a incorrect classification. So a criteria for checking the goodness of the classification procedure could be the probability of incorrect classification that means we call it the probability of misclassification.

So if the probability of the misclassification remains low then it is a good procedure. So it is something like in the testing of hypothesis problem where we accept or reject the hypothesis based on the sample. Now the hypothesis could have been true and we would have rejected it and the hypothesis could have been false and we could have accepted there were the two kinds of errors.

But when we are dealing with the k population here in the classification then the probability of misclassification or the probability of correct classification also becomes manifold that means an observation could have belonged to π_1 and we classify it as π_2 then observation could have been from π_1 we could have classify it as π_3 and so on and similarly the other way round that means the observation could be from any of the π_j .

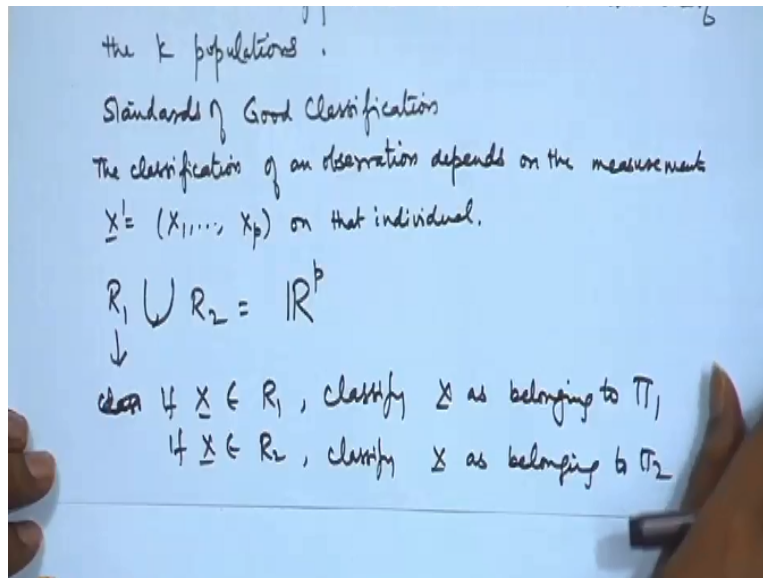

And we can classify it as one of the π_i . Along with that we can also have the cost of misclassification along with the probability another additional thing could be that if you do the wrong classification then there can be some additional cost. So in a general decision theoretic setup one can also consider that. The particular case can be that if you have a correct classification you have no loss and if no cost is implemented.

And if you make a wrong classification then you are incurring say one cost then you can get a 0, 1 loss function kind of thing. So now let me give some notation here the classification of an observation depends on the measurements= x_1, x_2, \dots, x_p on that individual. So we can

actually consider R_1 and R_2 as a partition of the p dimensional space here where R_1 is the space where classify that is if x belongs to say R_1 classify x as belonging to π_1 .

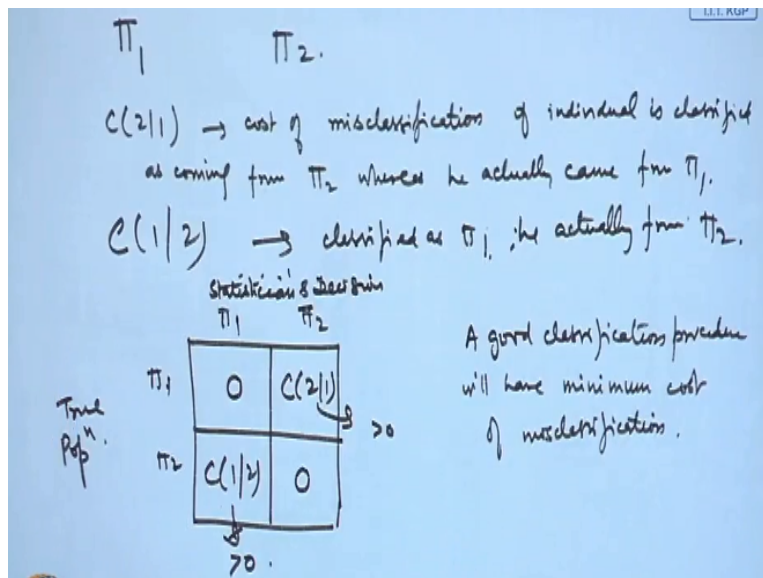

And if x belongs to R_2 .

(Refer Slide Time: 43:05)

Then you classify x as belonging to π_2 . This R_1 and R_2 are disjoint regions in the p dimensional sample space.

(Refer Slide Time: 43:25)

I mentioned about the kind of errors suppose in the beginning we consider only 2 populations say π_1 and π_2 . So we may consider $C(2|1)$ as the cost of misclassification if individual is classified as coming from π_2 whereas he actually came from π_1 . Similarly, we can consider $C(1|2)$ that is classified as π_1 and he actually came from π_2 . So we have 2 cost of

misclassification.

So in a decision theoretic setup if we consider it as a loss metric we can guide it in this fashion π_1, π_2 that is the statistician decision and on this side we have π_1, π_2 that is the true population. So if the true population is π_1 we classify it as π_1 then there is a 0 cost. Similarly, if true population is π_2 and we classify as π_2 then also it is 0. If the true population is π_1 and we classify it as 2 then the cost is C_{12} and similarly here the cost is C_{21} .

So these two terms are taken to be positive in general. A good classification procedure will have minimum cost of misclassification. As we have seen in the previous discussion in general in the statistical decision making problem it is not possible to completely minimize the misclassification cost like in the case of testing of hypothesis problems also we have seen that the type 1 error and the type 2 error cannot be completely eliminated.

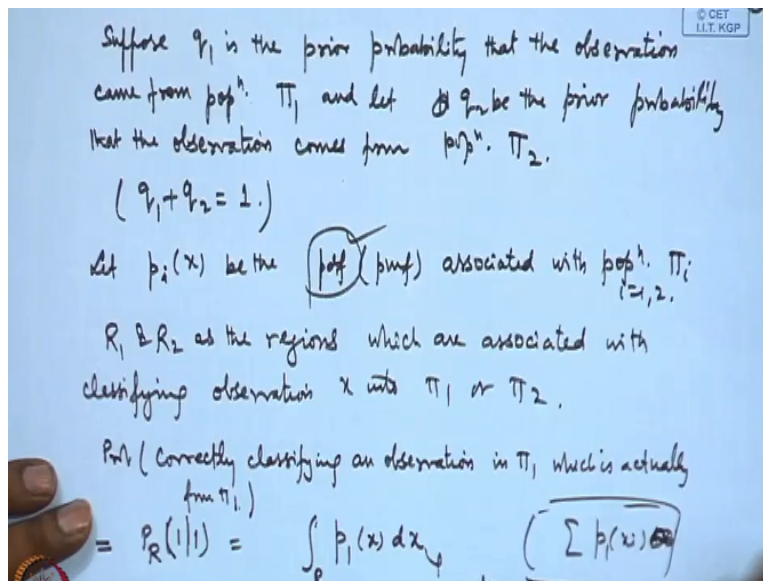

So there was a compromise which was worked out that you can consider fixed level of significance and then you consider the probability of type 2 error to be the smallest or the power of the test to be the maximum. So this was one of the compromise solutions that we considered. So if we consider it as a true population then it is actually a part of you can consider it as a testing of hypothesis problem.

And therefore both cannot be minimized simultaneously. So let us consider here this cost function and in what way we can consider the minimization etcetera. So one type of terminology which we did not consider in the testing of hypothesis problem is to allocate prior probabilities to each of the population. For example, if we know that both the population may occur with equal probabilities or the population 1 may occur with probability $1/3$.

And population 2 may occur with probability $2/3$ and so on. For example, you get a satellite image and you want to classify whether it is a land area or whether it is a water area. So if the image is taken from the satellite of the earth area a portion of the earth then you know that earth area is say the land area in the whole earth is $1/4$ and the water area is $3/4$. So you can allocate the probability p_1 and p_2 the prior probability.

So if you have the prior probabilities then we can reduce this number the probability of misclassification to a single number. So you can consider the Bayesian Classification Rules.

(Refer Slide Time: 48:18)

So let me introduce this here now. Suppose q_1 is the prior probability that the observation came from population π_1 and let q_2 be the prior probability that the observation comes from population π_2 . So here of course $q_1 + q_2$ should be $=1$. Let us consider say $p_i(x)$ is the so you may have a discrete or continuous distribution or it could be mixture also, but in particular let us take either purely discrete or purely continuous.

So you will have a pdf or pmf associated with the population π_i and we are considering R_1 and R_2 as the regions which are associated with classifying observation x into π_1 or π_2 . So we define probability of correctly classifying an observation in π_1 which is actually from π_1 . This we write as $P_R(1|1)$. This we can write as $\int_{R_1} p_1(x) dx$. So I am considering actually the density function form if it is a discrete case we can equivalently change it to the summation also.

So I am not discussing this case separately let us have this interpretation. So this dx is actually it would be multivariate because it depends upon what kind of observation you are having. In general, we may be dealing with multivariate observations here.

(Refer Slide Time: 51:34)

The Prob of misclassifying an observation from π_1

$$= P_R(2|1) = \int_{R_2} p_1(x) dx$$

Prob of correctly classifying an observation of π_2

$$P_R(2|2) = \int_{R_2} p_2(x) dx$$

Prob of misclassifying an observation from π_2

$$P_R(1|2) = \int_{R_1} p_2(x) dx$$

So similarly we can define the probability of misclassifying an observation from π_1 that is P_{R2} given 1 that means it is coming from 1 we classify it as 2 that means the density is actually p_1 , but we put it as R_2 . And in a similar way we have the probability of correctly classifying an observation of π_2 that will be $P_{R2/2}$ and probability of misclassifying an observation from π_2 that we will write as $P_{R1/2}$. That will be integral $p_2(x) dx$ R_1 .

(Refer Slide Time: 53:08)

Expected loss from costs of misclassification

$$E = C(2|1) P_R(2|1) q_1 + C(1|2) P_R(1|2) q_2$$

A procedure R that divides \mathcal{X} into R_1 & R_2
sample space of x
such that E is minimized for given q_1 & q_2 is called a Bayes procedure.

When there is no prior information about the probabilities of each popⁿ, then we consider expected loss of the observation is from π_1 ,

$$r_R^{(1)} = C(2|1) P_R(2|1)$$

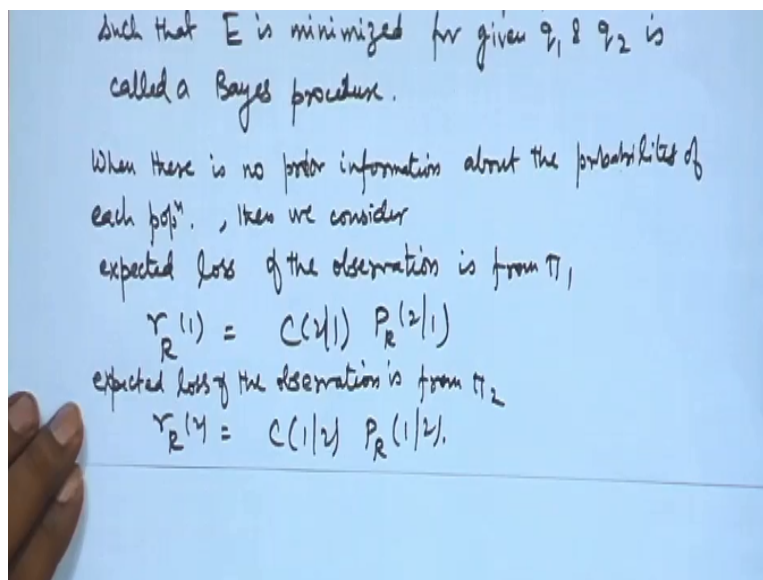

So we can consider now expected loss from cost of misclassification. Let us call it E that will be $=C/2/1 P_{R2/1} q_1 + C/1/2 P_{R1/2} q_2$. Let me explain this if the observation is from 1 so the prior probability of the population 1 is q_1 and we are incorrectly classifying it into 2. So the probability is this and we also incur a cost $C/2/1$ of misclassification. Similarly, if the population is actually 2 then the prior probability is q_2 .

And we misclassify it as 1 so the probability of that is $P_{R(1|2)}$ and then the cost of misclassifying an observation from 2 into 1 that is $C(1|2)$. So this becomes the expected loss. So a procedure R that divides R_n into R_1 and R_2 . So we consider this sample space say x not in R_n because I have not mentioned the dimension here. Let us consider x here this is the sample space of x into R_1 and R_2 such that E is minimized for given q_1 and q_2 .

This is called a Bayes procedure. So we will mention that how to obtain a Bayes procedure here. There can be another way when there is no prior information then I will have 2 different terms that is the probability of misclassification from first one and the probability of misclassification on the second one. So let me define that also. When there is no prior information about the probabilities of each population.

Then we consider 2 terms. Expected loss if the observation is from π_1 that is we call $r_{R(1)}$ that is $=C(2|1)P_{R(2|1)}$ given 1.

(Refer Slide Time: 56:37)

And similarly expected loss if the observation is from π_2 that we call $r_{R(2)}$ that is $=C(1|2) P_{R(1|2)}$. We can give some decision theoretic definition which I will be explaining in the next lecture like we can call about a procedure being better than another procedure, a procedure being as good as another procedure and admissible procedure, a Minimax procedure and we will show that when the prior probabilities are known the Bayesian procedure can be determined.

When the prior probabilities are not known we will try to find out the Minimax procedure.

We will also develop the procedures for classification into multivariate normal populations.
So these things we will be covering in the following lecture.
