Lecture – 47
Chi-Square Distribution (contd.), t – distribution

We have introduced a sampling distribution called Chi-Square Distribution, and then I showed that if we are doing the sampling from a normal distribution then the distribution of the sample variance is a Chi-Square distribution therefore, chi square distribution is a sampling distribution. We used a moment generating function technique to derive the distribution of S square. Firstly, by proving that sample mean and sample variance are independently distributed, when we are sampling from a normal population.

Today I will give a alternative derivation by the method of transformations for the sampling distribution of X bar and S square when we are sampling from a normal population

(Refer Slide Time: 01:06)

So, let us consider that X_1, X_2, \dots, X_n is a independently and identically distributed normal μ σ^2 random variables. So, we want to derive the distribution of X bar that is sample mean $\frac{1}{n} \sum_{i=1}^n X_i$ and S square that is $\frac{1}{n-1} \sum_{i=1}^n (X_i - \bar{X})^2$. So, the method of proof will be through

transformation. So, we will consider a transformation of the set X_1, X_2, \dots, X_n in the following fashion

So, let us consider Helmert's orthogonal transformation; now this is a special transformation given in the following fashion that we define Y is equal to Y_1, Y_2, \dots, Y_n as $B X$ where B is the matrix of coefficients the first row is $1/\sqrt{n}, 1/\sqrt{n}$ and so on $1/\sqrt{n}$. The second row it is $-1/\sqrt{2}, 1/\sqrt{2}$ and remaining terms are 0. The third one is $-1/\sqrt{6}, 1/\sqrt{6}, 2/\sqrt{6}$ and the remaining terms are 0; likewise if we continue in the last row we have $-1/\sqrt{2n-2}, 1/\sqrt{2n-2}$ and so on finally, the last term is $(n-1)/\sqrt{n}$ multiplied by X_1, X_2, \dots, X_n .

So, first of all let us observe this B matrix this matrix is a special matrix which is called a Helmert's orthogonal matrix, the terms of the first row are same and if you take every next row then it is defined in such a way that if I multiply any 2 rows then the product will be 0, that is the scalar product of any 2 rows is 0 for example, if I take first and second then here it is $-1/\sqrt{2}$, and here it is $1/\sqrt{2}$, so if I multiply the sum will give me 0. Suppose I take this with this then again the same thing because these 2 terms are same, so if I multiply here and add then this will become 0.

Similarly, if I take these and multiply by the first row then $-1/\sqrt{6n}, 1/\sqrt{6n}$ plus $2/\sqrt{6n}$ so again the sum is equal to 0. So, this is a special matrix which is constructed for this purpose. Now let us see the effect of this, what we have done is that we have transformed the X_1, X_2, \dots, X_n variables to new variables called Y_1, Y_2, \dots, Y_n by means of this.

(Refer Slide Time: 04:32)

B is an orthogonal matrix $\Rightarrow BB^T = I = B^T B$
 $Y^T Y = X^T B^T B X = X^T X$ $|J| = 1$
 or $\sum_{i=1}^n Y_i^2 = \sum_{i=1}^n X_i^2$ $Y_1 = \sqrt{n} \bar{X}$
 $\sum_{i=2}^n Y_i^2 = \sum_{i=2}^n Y_i^2 - Y_1^2 = \sum_{i=2}^n X_i^2 - n\bar{X}^2 = \sum (X_i - \bar{X})^2$
 The joint density of X_1, \dots, X_n is
 $f_X(x) = \frac{1}{(\sigma\sqrt{n})^n} e^{-\frac{1}{2\sigma^2} \sum (x_i - \mu)^2}$
 $= \frac{1}{(\sigma\sqrt{n})^n} e^{-\frac{1}{2\sigma^2} (\sum x_i^2 - 2\mu \sum x_i + n\mu^2)}$

So, we have B is an orthogonal matrix and we have BB^T is equal to identity matrix. So, if I consider $Y^T Y$ then that is equal to $X^T B^T B X$ that is equal to $X^T X$. So, this is also $B^T B$ that is equal to $X^T X$; that means, $\sum Y_i^2$ is equal to $\sum X_i^2$ for $i = 1$ to n . That means, the original sum of squares is equivalent to the new sum of squares, also we can see here by this transformation that Y_1 is equal to $\sqrt{n} \bar{X}$; because if I consider the multiplication of this matrix with this vector and look at the first term and the first term will be X_1 by \sqrt{n} plus X_2 by \sqrt{n} plus X_n by \sqrt{n} . So, that is $\sqrt{n} \bar{X}$. So, Y_1 is $\sqrt{n} \bar{X}$.

So, from here we get $\sum_{i=2}^n Y_i^2$ is equal to $\sum_{i=2}^n X_i^2 - Y_1^2$ which is same as now $\sum_{i=2}^n X_i^2 - n\bar{X}^2$, that is equal to $\sum_{i=2}^n (X_i - \bar{X})^2$, which is the term which appears in the S^2 term that is the sample variance. Therefore, this new transformation is giving me Y_1 as well as S^2 , that is which is \bar{X} which is a term of \bar{X} and which is another term which is a term of S^2 . So, our desired objective was to get the distributions of \bar{X} and S^2 and this particular transformation helps us in at least representing these 2 terms in terms of transformed variables.

Now, let us look at the distribution so. Firstly, we write down the joint density function of X_1, X_2, \dots, X_n . So, each of these X_i 's are normal μ σ^2 variables. So, that distribution we write as $\frac{1}{(\sigma\sqrt{2\pi})^n} e^{-\frac{1}{2\sigma^2} \sum_{i=1}^n (X_i - \mu)^2}$. Now this we expand we can write as $\frac{1}{(\sigma\sqrt{2\pi})^n} e^{-\frac{1}{2\sigma^2} (\sum_{i=1}^n X_i^2 - 2\mu\sqrt{n}X_1 + n\mu^2)}$. So, Jacobian of the transformation that will be having absolute value 1; so this will be used for calculation of the transform density.

When we consider the transformation Y is equal to BX and B is an orthogonal matrix, then we know that the determinant of an orthogonal matrix is either plus 1 or minus 1. So, Jacobian of the transformation that will be having absolute value 1; so this will be used for calculation of the transform density.

(Refer Slide Time: 08:09)

The joint density of Y_1, \dots, Y_n is, then

$$f_Y(\underline{y}) = \frac{1}{(\sigma\sqrt{2\pi})^n} e^{-\frac{1}{2\sigma^2} \left(\sum_{i=1}^n Y_i^2 - 2\mu\sqrt{n}Y_1 + n\mu^2 \right)}$$

$$= \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{1}{2\sigma^2} (Y_1 - \sqrt{n}\mu)^2} \prod_{i=2}^n \frac{1}{(\sigma\sqrt{2\pi})^{1/2}} e^{-\frac{Y_i^2}{2\sigma^2}}$$

$Y_i \in \mathbb{R}, i=1, \dots, n$

We conclude from the above expression, that Y_1, \dots, Y_n are independently distributed &

$$Y_1 \sim N(\sqrt{n}\mu, \sigma^2), \quad Y_i \sim N(0, \sigma^2), \quad i=2, \dots, n.$$

$$\Rightarrow X = \frac{Y_1}{\sqrt{n}} \sim N(\mu, \sigma^2/n) \quad \& \quad \sum_{i=2}^n \frac{Y_i^2}{\sigma^2} \sim \chi_{n-1}^2$$

So, if I consider the joint density of Y_1, Y_2, \dots, Y_n then it is obtained as. So, in the density of X_1, X_2, \dots, X_n let us substitute the transformed values in terms of Y_i 's. So, $\sum_{i=1}^n X_i^2$ will become $\sum_{i=1}^n Y_i^2$, and this $\sum_{i=1}^n X_i$ is nothing, but $\sqrt{n}X_1$. Now X_1 is Y_1/\sqrt{n} . So, this also we can substitute and multiplied by the Jacobian of the transformation that is unity. So, we get the transformed density as $\frac{1}{(\sigma\sqrt{2\pi})^n} e^{-\frac{1}{2\sigma^2} (\sum_{i=1}^n Y_i^2 - 2\mu\sqrt{n}Y_1 + n\mu^2)}$. So, we get the transformed density as $\frac{1}{(\sigma\sqrt{2\pi})^n} e^{-\frac{1}{2\sigma^2} (\sum_{i=1}^n Y_i^2 - 2\mu\sqrt{n}Y_1 + n\mu^2)}$. So, we get the transformed density as $\frac{1}{(\sigma\sqrt{2\pi})^n} e^{-\frac{1}{2\sigma^2} (\sum_{i=1}^n Y_i^2 - 2\mu\sqrt{n}Y_1 + n\mu^2)}$. So, we get the transformed density as $\frac{1}{(\sigma\sqrt{2\pi})^n} e^{-\frac{1}{2\sigma^2} (\sum_{i=1}^n Y_i^2 - 2\mu\sqrt{n}Y_1 + n\mu^2)}$.

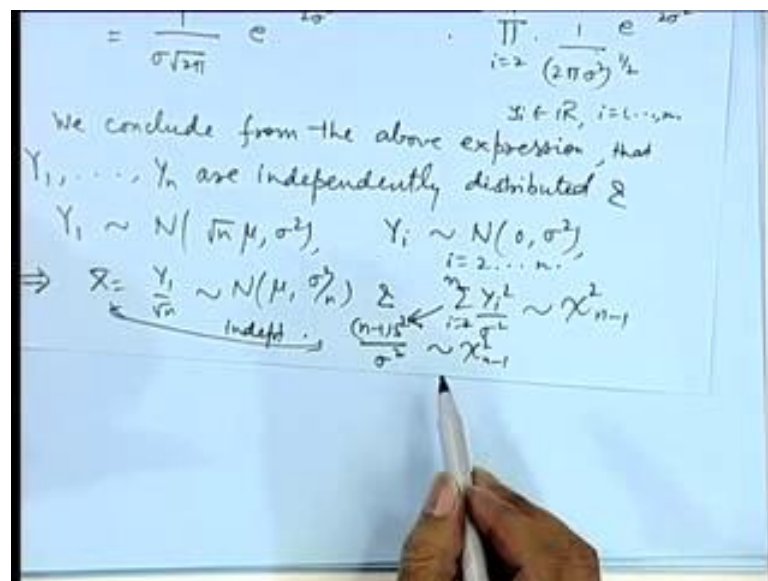

Now, in this particular exponent if I consider this $\sum_{i=1}^n Y_i^2$ I take I write this as $Y_1^2 + \sum_{i=2}^n Y_i^2$. Now this $Y_1^2 - 2\mu\sqrt{n}Y_1 + n\mu^2$

$1 + n \mu^2$ becomes a perfect square. So, we can represent it as $1 + \frac{\mu^2}{\sigma^2} \sum_{i=1}^n Y_i^2$ and the other terms we write separately as $\prod_{i=2}^n \frac{1}{\sigma \sqrt{2\pi}} e^{-\frac{Y_i^2}{2\sigma^2}}$. The range of the transformed variables each of these Y_i 's are also from minus infinity to plus infinity.

Now, you see this representation we are able to express the joint density of Y_1, Y_2, \dots, Y_n as product of the certain functions where each function is strictly dependent only on each Y_i . So, these are n functions. So, this is a function which is dependent upon Y_1 alone and here we have $n-1$ function each function is dependent upon Y_2, Y_3, \dots, Y_n respectively. So, if we integrate with respect to Y_i 's we will get individual terms; that means, Y_1, Y_2, \dots, Y_n are independent and you are also able to say that these Y_i 's are independently normally distributed, because of the form of the density. So, we conclude that we conclude from the above expression that Y_1, Y_2, \dots, Y_n are independently distributed and Y_1 follows normal $\sqrt{n}\mu$ and σ^2 and remaining Y_i 's follow normal 0 and σ^2 for $i = 2$ to n .

So, this implies that since Y_1 is $\sqrt{n} \bar{X}$, that is \bar{X} that is equal to Y_1 by \sqrt{n} that will follow normal μ and σ^2/n and the sum of the squares of this Y_i 's divided by σ^2 that is $\sum_{i=2}^n \frac{Y_i^2}{\sigma^2}$ that will follow chi square on $n-1$ degrees of freedom.

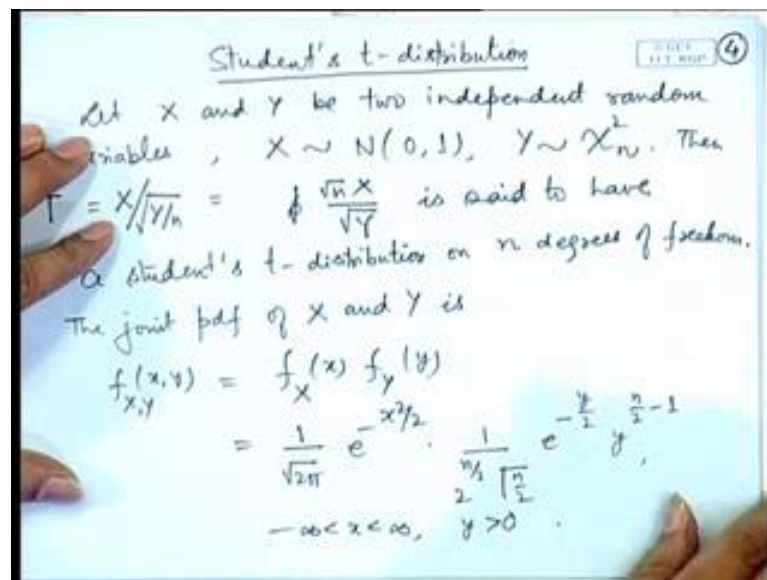

(Refer Slide Time: 12:28)

But this term is nothing, but n minus 1 S square by σ square. So, that is following chi square on n minus 1 degrees of freedom and further these 2 are independent.

So, the result which we had proved using moment generating function, we have proved using transformations of the variables also. This Helmert's orthogonal transformation is quite useful, and that actually suggests that a procedure for obtaining the distributions of the sums of random variables and the squares of random variables. So, many times this statement is quite useful.

(Refer Slide Time: 13:21)

Now, we move over to another sampling distribution called t distribution. So, we call it students t -distribution, there is a story behind that why it is called a student's t -distribution, basically it was discovered by W.S Gosset a statistician in England; however, he worked in a brewery and therefore, it was not permitted for him to give his affiliation as working in a brewery. So, he used a pseudo name student and therefore, the distribution became famous as students t -distribution.

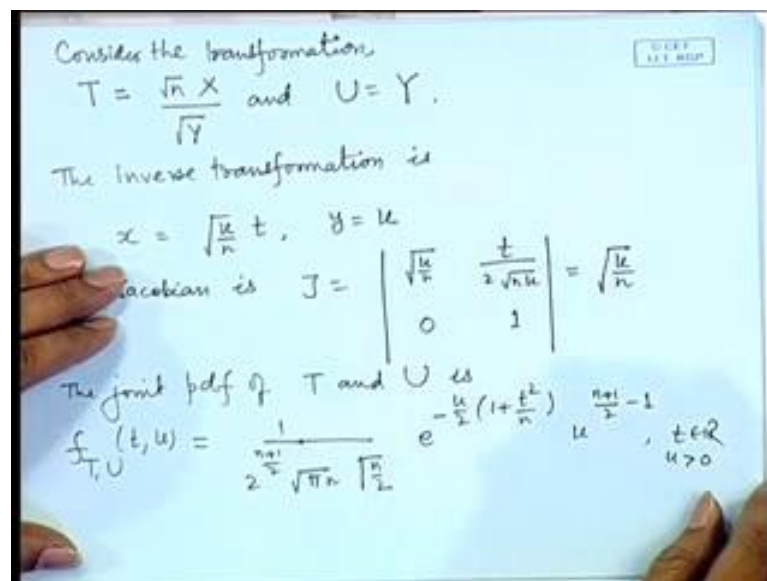

So, if I have let X and Y be 2 independent random variables, let us assume that X follows normal $0, 1$ distribution and Y follows a chi square distribution on n degrees of freedom. If I consider the ratio X divided by Y by n and square root. So, let me write it as square root n X by square root of Y , let me call it say T , then this T is said to have a student's t -distribution on n degrees of freedom.

Now, this degrees of freedom terminology is coming from the chi square distribution, where we express that what is the meaning of the terms degrees of freedom, a chi square distribution on n degrees of freedom was represented as the sum of squares of n independent standard normal random variables. So, in the definition of t distribution I am using the degrees of freedom of chi square, and therefore, this t distribution is said to have set to be on n degrees of freedom.

Now, since here X and Y are independently distributed random variables, the derivation of the density of t is an exercise of deriving distribution of a function of random variables. So, we can write down the joint distribution of X and Y and create a transformation, in which one of the variables will be defined by t , and some other variable and we derive the distribution.

So, let us do it in the following way. Firstly, we look at the joint probability density function of X and Y . So, it is equal to the product of the individual distributions of X and Y . Now X is normal $0, 1$ so the density is 1 by root 2π , e to the power minus X square by 2 , and the density of Y is chi square n that is 1 by 2 to the power n by 2 , gamma n by 2 , e to the power minus Y by 2 , Y to the power n by 2 minus 1 . Here the range of the X variable is from minus infinity to infinity and range of Y variable is positive.

(Refer Slide Time: 17:01)

So, now we are considering the transformation T is equal to root n X by root Y . So, let us consider this transformation. So, the second variable we can consider as say V is equal to

or say U is equal to Y, because we have to consider a one to one transformation or at least the number of variables should be same, so that we can find the joint density and then we can integrate out the not desired variable.

So, the inverse transformation here will be. So, x is equal to root u by n t and y is equal to u. So, we consider the Jacobian del x by del t that is root u by n, del x by del u that is t by 2 root n u, del y by del t that is 0 and del Y by del u that is 1. So, it is equal to root u by n. So, if we substitute this in the joint density of X Y and multiplied by Jacobian, we get the joint probability density function of T and U f T, U.

So, let us substitute the values here 1 by root 2 pi and all this thing is constant, so we combine it together, it becomes 1 by 2 to the power n plus 1 by 2, root pi n, gamma n by 2, e to the power minus u by 2, 1 plus t square by n, u to the power n plus 1 by 2 minus 1. So, this is after combining the coefficients and another thing you observe here that if we are making this particular transformation, the range of T remains from minus infinity to infinity and U is the chi square variable. So, U is positive. So, t belongs to r and u is positive.

To get the density of T we integrate this joint density with respect to U. So, if you integrate with respect to U from 0 to infinity you observe this term, it is e to the power minus u into something, and then u to the power some power, which is of the nature of a gamma integral or a gamma function.

(Refer Slide Time: 20:20)

The marginal pdf of T is

$$f_T(t) = \int_0^{\infty} f_{T,U}(t,u) du = \frac{\Gamma\left(\frac{n+1}{2}\right)}{\Gamma\left(\frac{n}{2}\right) \sqrt{n}} \left(1 + \frac{t^2}{n}\right)^{-\frac{n+1}{2}}, \quad -\infty < t < \infty$$

$$= \frac{1}{\sqrt{n} B\left(\frac{n}{2}, \frac{1}{2}\right)} \left(1 + \frac{t^2}{n}\right)^{-\frac{n+1}{2}}, \quad -\infty < t < \infty.$$

The density is symmetric about $t=0$. Hence all odd ordered moments vanish (provided they exist). Even ordered moments exist of order $< n$.

$$E(T^k) = \frac{\Gamma\left(\frac{k+1}{2}\right) \Gamma\left(\frac{n-k}{2}\right)}{\Gamma\left(\frac{n}{2}\right) \Gamma\left(\frac{n}{2}\right)}$$

So, it can be easily evaluated and we get the marginal probability density of T is let me call it f_U that is $\int_{-\infty}^{\infty} f_{T,U} du$ from this is f_T . So, I have written wrongly this is f_T from 0 to infinity.

So, here the order of the gamma function is $n + 1/2$. So, in the numerator I will get $\Gamma(n + 1/2)$ divided by u as a multiple half, $1 + t^2$ square by n . So, in the denominator I will get $\Gamma(n/2)$ $\pi^{n/2}$ $(1 + t^2)^{n/2}$. Now there is a 2 to the power $n + 1/2$ term that will cancel out, so we are left with this density as $\Gamma(n + 1/2)$ divided by $\Gamma(n/2)$ $\pi^{n/2}$ $(1 + t^2)^{n/2}$ and the range of the variable is from minus infinity to infinity so this is the density of the t distribution on n degrees of freedom.

This particular coefficient we can write in a slightly different way also, because $\pi^{n/2}$ if we observe it is $\Gamma(1/2)$. So, we can utilize the beta function notation and it becomes $1/\sqrt{n}$ $\beta(n/2, 1/2)$ and $(1 + t^2)^{-n/2}$.

Obviously if you look at this one the density is a symmetric function in t around 0, because if we replace t by $-t$ you get the same function. Another thing you observe that as t becomes large this will go towards 0, because the $(1 + t^2)^{n/2}$ term is in the denominator; also you observe that higher the power of n higher the value of n the conversions to 0 will be faster. So, basically that determines the shape of the t distribution, so we look at this thing.

The density is symmetric about $t = 0$, hence all odd ordered moments vanish provided they exist, even ordered moments can be calculated. Now if you evaluate $E(t^{2k})$ integral of this term, then you can reduce it to a gamma function and do the calculation. So, the even ordered moments exist of order less than n . So, we have expectation of T to the power k for the even ordered moment as n to the power $k/2$, $\Gamma(k/2 + 1/2)$, $\Gamma(n - k/2)$ divided by $\Gamma(n/2)$.

(Refer Slide Time: 24:17)

In particular $E(T) = 0$, $E(T^2) = V(T) = \frac{n}{n-2}$ $n > 2$

$\mu_4 = E(T^4) = \frac{3n^2}{(n-2)(n-4)}$, $n > 4$

$\beta_2 = \frac{\mu_4}{\mu_2^2} - 3 = \frac{3(n-2)}{n-4} - 3 = \frac{6}{n-4} > 0$

So the density of T is leptokurtic.

Let X_1, \dots, X_n i.i.d. $N(\mu, \sigma^2)$

Then \bar{X} & S^2 are independent

$\bar{X} \sim N(\mu, \sigma^2/n) \Rightarrow \frac{\sqrt{n}(\bar{X} - \mu)}{\sigma} \sim N(0, 1)$

$\frac{(n-1)S^2}{\sigma^2} \sim \chi_{n-1}^2$

So, in particular expectation of T is 0, expectation of T square is that is variance of T that is n by n minus 2 which is existing for n greater than 2. You observe this is somewhat peculiar number n by n minus 2, as n becomes large this becomes close to 1.

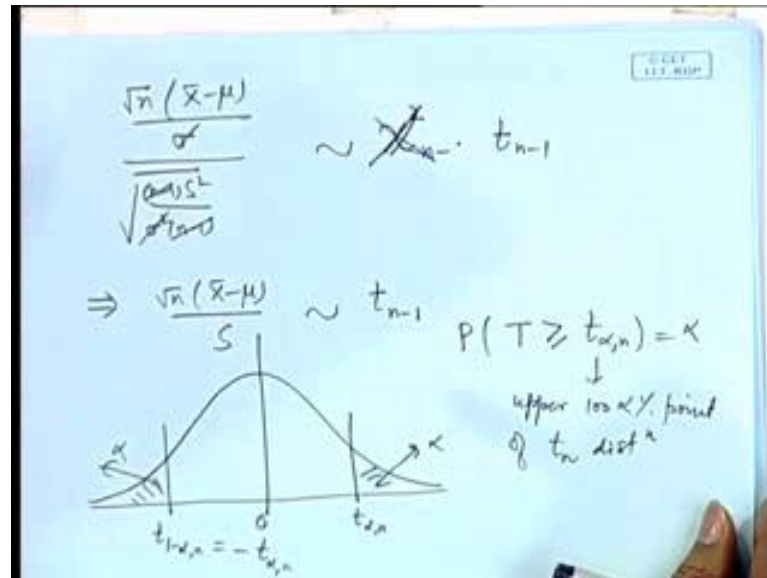

μ_4 is expectation of T to the power 4, that is $3n^2$ by n minus 2 into n minus 4, which is valid for n greater than 4. So, we can calculate the measure of kurtosis that is β_2 , that is μ_4 by μ_2 square minus 3. So, you look at this term we divide by n square, so this cancels out and we get 3 into n minus 2 by n minus 4 minus 3, which is simply 6 by n minus 4 so; obviously, this is positive, because we are considering n to be greater than 4, but you can observe here that if n becomes sufficiently large, then this number becomes small and that means, the kurtosis moves towards normality as n becomes large; in general it is leptokurtic density of T is Leptokurtic.

Now, let us consider this distribution as a sampling distribution, because right now I have given a distributional theoretic representation of this t variable, because we are writing it as only ratio of 2 variables in a particular form, but we can make use of the fact that chi square is itself is a sampling distribution, so whether we can represent t also in the same fashion. So, let us see.

If I consider a random sample from normal μ σ^2 distribution, then \bar{X} and S^2 are independent that we proved and what are the distributions? \bar{X} follows normal μ σ^2 by n , this means that I can consider $\sqrt{n}(\bar{X} - \mu)$ by

sigma and this will follow normal $0, 1$ n minus 1 s square by sigma square follows chi square on n minus 1 degrees of freedom, and this variable and this variable is independent.

(Refer Slide Time: 27:30)

So, if I make use of this definition of the 2 variables of the t variable, then I can write root n \bar{X} minus μ by sigma divided by root n minus 1 S square by sigma square into n minus 1 , this must follow chi square distribution on n minus 1 sorry this must follow t distribution on n minus 1 degrees of freedom. Now if you simplify this term here n minus 1 cancels out sigma cancels out. So, we are left with root n \bar{X} minus μ by S , this follows t distribution on n minus 1 degrees of freedom therefore, t distribution is a sampling distribution.

Another interesting thing is you can observe when I considered root n \bar{X} minus μ by sigma this is standard normal, and here root n \bar{X} minus μ by S is there; that means, sigma is replaced by S , later on we will see in the inference portion that S is actually an estimate for sigma. So, when sigma is not known we have to work with S and the distribution of that is known. In fact, in the context of this only this distribution was derived.

Now, regarding the probability points of t distribution, so the t distribution is a symmetric distribution about 0 . So, if this point I call $t_{\alpha, n}$, then the probability beyond this must be α ; that means, probability of T greater than or equal to $t_{\alpha, n}$

is equal to alpha; that means, $t_{1-\alpha, n}$ is upper 100 alpha percent point of t distribution on n degrees of freedom. Because of the symmetry if you consider $t_{1-\alpha, n}$ then that will be equal to $t_{\alpha, n}$; that means, if this value is alpha, then this point is $t_{1-\alpha, n}$ by this definition, but because of the symmetry this will be equal to $t_{\alpha, n}$.

Now, few things that we observe let us recollect that; when I wrote the density I said it is symmetric about 0 the odd ordered moments vanish even ordered moments can be found, mean is 0, the variance approaches 1 as n becomes large, the peakedness approaches normal p as n becomes large. So, these things and another thing I said that if you replace sigma by S then you have a t distribution, here you have a normal distribution.

This shows some sort of close similarity between t distribution and n t distribution and a standard normal distribution. Actually it is true; in fact we can prove that as n becomes large, the t distribution can be approximated by a standard normal distribution. So, we prove the following result.

(Refer Slide Time: 30:55)

Theorem: Let $T \sim t_n$. As $n \rightarrow \infty$ the pdf of T converges to $\phi(t) = \frac{1}{\sqrt{2\pi}} e^{-t^2/2}$.

Pf. $f_T(t) = \frac{\Gamma(\frac{n+1}{2})}{\Gamma(\frac{n}{2}) \sqrt{\pi n}} \left(1 + \frac{t^2}{n}\right)^{-\frac{n+1}{2}}$

As $n \rightarrow \infty$, $\left(1 + \frac{t^2}{n}\right)^{-\frac{n+1}{2}} \rightarrow e^{-t^2/2}$

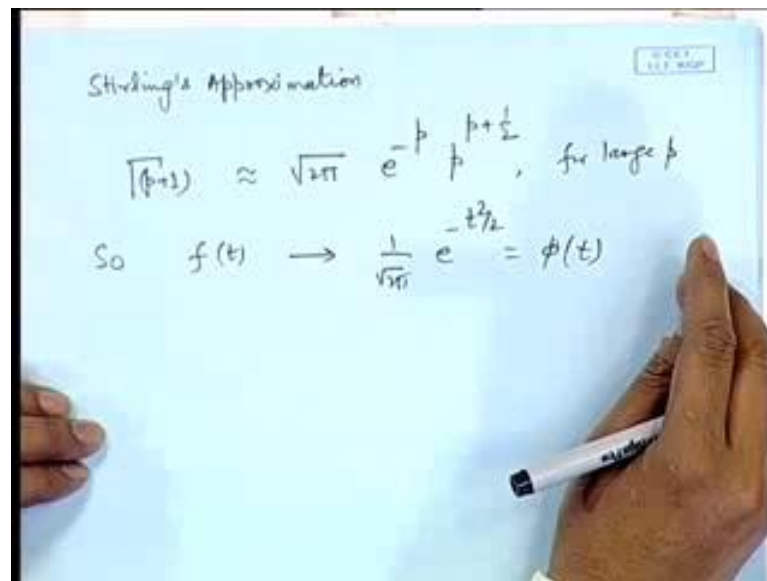

$$\frac{\Gamma(\frac{n+1}{2})}{\Gamma(\frac{n}{2}) \sqrt{\pi n}} \approx \frac{\sqrt{2\pi} e^{-\frac{1}{2}} \cdot \left(\frac{n-1}{2}\right)^{\frac{n-1}{2}}}{\sqrt{\pi n} \sqrt{2\pi} e^{-\frac{n-1}{2}} \cdot \left(\frac{n-2}{2}\right)^{\frac{n-1}{2}}}$$

So, we consider let T be a t random variable on n degrees of freedom, then as n becomes large the pdf of T converges to phi t. Phi t is the probability density function of a standard normal random variable. So, to prove this let us write down the density function of t as derived that is gamma n plus 1 by 2 divided by gamma n by 2 root pi n and 1 plus

t^2 by n to the power minus n plus 1 by 2 . Now you observe this term as n becomes large or n tends to infinity, this converges to e to the power minus t^2 by 2 .

So, as n tends to infinity, 1 plus t^2 by n to the power minus n plus 1 by 2 converges to e to the power minus t^2 by 2 . So, let us look at the remaining terms we must actually prove that this remaining term converges to 1 by $\sqrt{2\pi}$. So, if we look at this term n plus 1 by 2 , $\Gamma(\sqrt{2\pi n})$.

(Refer Slide Time: 32:48)

Now, there is a formula called Stirling's approximation. So, Stirling's approximation is let me write it here, that $\Gamma(p+1)$ can be approximated by $\sqrt{2\pi}$, e to the power minus p , p to the power p plus half for large p ; that means, for large p gamma function can be approximated by an exponential and binomial type of term. So, is a mathematical formula we can use it here. So, I am saying n is large then I can represent these things as $\sqrt{2\pi}$, e to the power minus n minus 1 by 2 , n minus 1 by 2 to the power n plus 1 by 2 , no n minus 1 by 2 by to the power n by 2 and in the denominator you have $\sqrt{2\pi}$, e to the power minus n minus 2 by 2 , n minus 2 by 2 to the power n minus 1 by 2 .

So, we can do some simplification this $\sqrt{2\pi}$ etcetera will cancel out, and here you have 1 by 2 to the power n by 2 , and 1 by 2 to the power n minus 1 by 2 . So, 1 by 2 will come here.

(Refer Slide Time: 34:22)

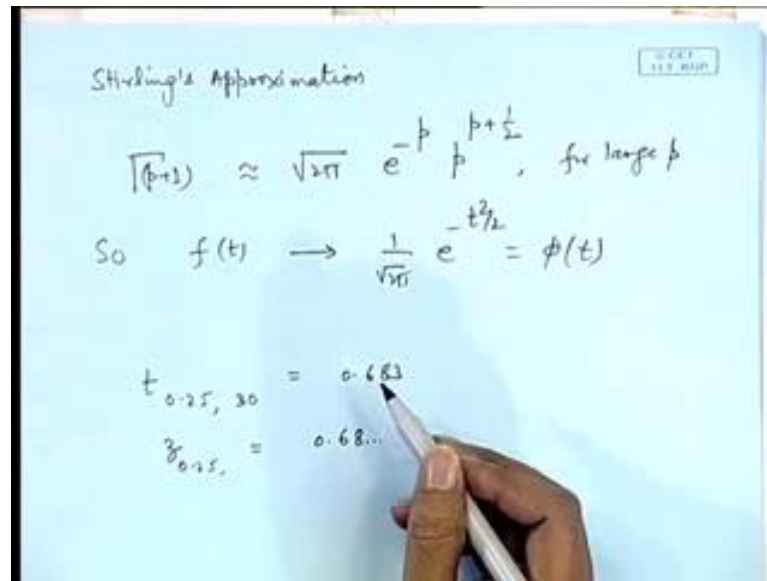

The image shows a whiteboard with handwritten mathematical work. At the top, it states: "As $n \rightarrow \infty$, $\left(1 + \frac{t^2}{n}\right)^{-\frac{n}{2}} \rightarrow e^{-\frac{t^2}{2}}$ ". Below this, there is a complex fraction representing the limit of the normal distribution density function. The numerator is $\frac{1}{\sqrt{2\pi n}} \left(\frac{1}{n}\right)^{\frac{n-1}{2}}$ and the denominator is $\frac{1}{\sqrt{2\pi n}} \frac{e^{-\frac{t^2}{2}}}{n^{\frac{n-1}{2}}}$. The final result shown is $\frac{1}{\sqrt{2\pi}}$.

So, this is giving rise to 1 by root 2 pi and then we get this e to the power half and here I can take common n in the numerator and denominator. So, those terms are getting canceled out that is n to the power n by 2, in the denominator I have n to the power half here and n to the power n minus 1 by 2. So, these all terms get canceled out and you are left with 1 minus 1 by n to the power n by 2, divided by 1 minus 2 by n to the power n minus 1 by 2.

So, if I take the limit as n tends to infinity, this goes to e to the power half and this goes to e therefore, the limit is simply 1 by root 2 pi, because this e to the power half e to the power half and e, they get canceled out. So, this proves that this f t converges to; f t converges to 1 by root 2 pi, e to the power minus t square by 2 that is the density function of a standard normal variance.

The question arises that for what sufficiently large value of n is this approximation good? The answer is that for n greater than or equal to 30, the approximation is extremely good and the tables of t distribution most of the times they show. So, if we look at a standard table of t distribution, unfortunately this cannot be seen here, but I will just write here the t value say at 0.25 and 30 is 0.683.

(Refer Slide Time: 36:13)

Stirling's Approximation

$$\Gamma(\lambda+1) \approx \sqrt{2\pi} e^{-\lambda} \lambda^{\lambda+\frac{1}{2}}, \text{ for large } \lambda$$

So $f(t) \rightarrow \frac{1}{\sqrt{2\pi}} e^{-t^2/2} = \phi(t)$

$t_{0.25, 30} = 0.653$
 $z_{0.25} = 0.68\dots$

If I look at the same value for normal distribution then the point where the probability is 0.25 above the given point, it is 0.67 that is the if I consider that as z point, z 0.5 is equal to 0.68 and since this tables is given only up to 2 places, so I cannot predict here, but it is pretty close as you can see from there.

In fact, the tables are not given beyond 30 in most of the cases, because the approximation is extremely good. In fact, at 120 the value is almost equal.
