Lecture – 22
Orthogonality between the Subspaces

Welcome. In last class we took an example of rectangular matrix and looked into different subspaces associated with it and, observed that null space and row space, a perpendicular to each other. In a sense, any vector belonging to left null space is perpendicular to any vector in the column space, and same for column space and left null space. Also made a comment that if a vector right hand side vector b has some component along left null space, it will be away from it will coming out of the column space. And therefore, Ax is equal to b cannot be solved.

So, then this the these are due to the orthogonality between the spaces, null space, row space, left null space and column space. We will explore it in more detail and we will start looking into what is an orthogonal, what are orthogonal vectors, what is orthogonality, and look into the property of orthogonality between the fundamental subspaces.

(Refer Slide Time: 01:24)

Length of a vector

Measure of the magnitude of a vector is its norm.
If we have a vector (a_1, a_2, \dots, a_n) , L_p norm is defined as

$$L_p = \left(\sum_{i=1}^n |a_i|^p \right)^{1/p}$$

For different values of p , different norms are defined

Taxicab norm: $p=1$, $L_1 = |a_1| + |a_2| + \dots + |a_n|$

L_2 norm: $p=2$, $L_2 = (a_1^2 + a_2^2 + \dots + a_n^2)^{1/2}$ ← This is measure of length in 2D/3D and is also called Euclidian norm

L_∞ norm: $p=\infty$, $L_\infty = \max(|a_1|, |a_2|, \dots, |a_n|)$

IIT KHARAGPUR | NPTEL ONLINE CERTIFICATION COURSES

So, length first idea which is little away from what we are doing right now on matrices and the properties of matrices; we will look into the definition of length of a vector. And this is given the length of a vector is usually measured by the term norm, when measure of the magnitude of a vector is norm. If you have a vector a to an which is the vector belongs to \mathbb{R}^n L^p norm of the vector or p th norm of the vector; is defined as L^p is equal to absolute magnitude of each if each of the component raise to the power p , and then some all the components and 1 by p th root of that.

So, for different values of p different norms and defined; for taxicab norm is defined if p is equal to 1 which is L^1 , which is basically magnitude of each of the components of a and summation of that. L^2 norm is defined for p is equal to 2 which is L^2 is root over of a_1^2 plus a_2^2 up to a_n^2 . And L^∞ norm is defined for p is equal to infinity. So, all of these components are raised to the power infinity. And then we take 1 by infinite root of that. So, the only the largest component stays there because, 1 by infinity all the components raise to the power infinity, the largest components becomes very large.

And then only this stays when I take 1 by infinite root of that. So, it becomes the maximum of magnitude of all the components of the matrix. This norm definition of this norms are important and later we will see when we look into iterative solvers and try to find out that convergence will use the norms for finding out convergence. The L^2 norm is important because, if we think of a 2D or 3D vector, it is a length of the vector, and it is also called it is a measure of length it is also called Euclidean norm.

(Refer Slide Time: 03:45)

Length of a vector

Euclidean norm is considered as length of a vector $x = \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix}$

$$\|x\| = \sqrt{\|x\|^2} = \sqrt{x_1^2 + x_2^2 + \dots + x_n^2} = \sqrt{x^T x}$$

If we have two right-angle vectors: x and y

By laws of right angle triangle

$$\|x\|^2 + \|y\|^2 = \|x-y\|^2$$

$$\Rightarrow x_1^2 + x_2^2 + \dots + x_n^2 + y_1^2 + y_2^2 + \dots + y_n^2 = (x_1 - y_1)^2 + (x_2 - y_2)^2 + \dots + (x_n - y_n)^2$$

$$\Rightarrow x_1 y_1 + x_2 y_2 + \dots + x_n y_n = 0 \Rightarrow x^T y = 0$$

Zero dot product

If x & y are orthogonal they will have a zero dot product: $x^T y = 0$, $y^T x = 0$. When $x, y \in \mathbb{R}^n$.

Euclidean norm is considered as length of the vector if I have a vector $x = [x_1 \ x_2 \ \dots \ x_n]$ Euclidean. So, 2D, 3D it is visible x_1 's root of or x_1 square plus x_2 square or root of or x_1 square plus x_2 square plus x_3 square; use me the length of the diagonal. These are this can be visualized but, in higher dimensional vector this is found out in same way and they are considered as a length of the factor. And we can see L 2 norm is given as this form, 2 lines inside which x raise is root over of L 2 squared norm which is x_1 square plus 2 square plus x_n square is root over of x transpose x when x is a vector.

If we have a right angle triangle the equivalent of Pythagoras theorem, there is a law of right angle triangles still stays that that the square length of squared of the length of 2 sum of the square of the length of the 2 sides is equal to square of the length of the hypotenuse. So, we have vectors x and y , and the hypotenuse becomes x minus y , x minus y is not the vector; it my this is not the x minus y vector; x minus y vector any vector should go through origin this is translated to get the vector difference.

Anyway so, we can write by laws of right angle triangle x squared, plus y squared is equal to x minus y square. And we can expand them, and while and then by rearranging and cancelling terms from which side, we can write $x_1 y_1$ plus $x_2 y_2$ plus $x_n y_n$ is equal to 0, or x transpose y is equal to 0. So, if x and y are orthogonal, we get x transpose

y is equal to 0 or which is basically equivalent of dot product of the vectors x and y , the vectors we have 0 dot product.

So, we can write if x and y are orthogonal they will give a , they will have a x transpose y is equal to 0 or y transpose x is equal to, when x and y they must be vector in the same dimensional vector space belongs to \mathbb{R}^n ; is important because n can be anything, n can be more than 2 or 3. For 2 or 3 2 dimensional and 3 dimensional vector we know that perpendicular vectors we will give zero dot product. But they are higher dimensional vectors also if they are perpendicular they will give 0 dot product. We will go ahead with this definition of orthogonality.

(Refer Slide Time: 06:39)

Orthogonal vectors are independent

If non-zero vectors v_1, v_2, \dots, v_k are mutually orthogonal (every vector is perpendicular to every other), then those vectors are linearly independent

IIT KHARAGPUR | NPTEL ONLINE CERTIFICATION COURSES

If non-zero vectors are so, this idea is orthogonal vectors are independent. If non-zero vectors v_1 up to v_k are mutually orthogonal, every vector is perpendicular to every other bracket close here. Then these vectors are linearly independent. So, you so, this is like if I have one vector 2 perpendicular vector they are linearly independent if I get another perpendicular vector in \mathbb{R}^3 they will be linearly independent. In \mathbb{R}^4 if we get some way another perpendicular vectors the all these vectors are perpendicular to each other. They will be linearly independent.

(Refer Slide Time: 07:35)

Orthogonal vectors are independent

If non-zero vectors v_1, v_2, \dots, v_k are mutually orthogonal (every vector is perpendicular to every other), then those vectors are linearly independent

Proof: Take $c_1 v_1 + c_2 v_2 + \dots + c_k v_k = 0$ and show that $c_1 = c_2 = \dots = c_k = 0$

$v_j^T v_i = 0$ for $i \neq j$, as the vectors are orthogonal

So, multiplying the first equation with v_j^T , we get $c_j v_j^T v_j = 0$ as all other terms vanish.

As v_j is non-zero, the coefficient must be zero. So: $c_j = 0$

Similarly, we can show by multiplying with other vectors $c_2 = \dots = c_k = 0$

So, mutually orthogonal vectors are mutually independent

IIT KHARAGPUR NPTEL ONLINE CERTIFICATION COURSES

So, the proof is that considered the orthogonal vectors. These vectors are mutually orthogonal. So, each vector dot product with other any other of the vector is 0. So, and now for linear independence we have to combine them and show that the coefficients are 0. So, take $c_1 v_1 + c_2 v_2 + \dots + c_k v_k = 0$ and show that c_1, c_2, c_k is equal to 0. If they are independent, if they are orthogonal then $v_1^T v_i = 0$ for $i \neq 1$ as the vectors are orthogonal.

So, what we will do? We will multiply this equation with v_1^T , which will be $v_1^T v_1 + c_2 v_1^T v_2 + \dots + c_k v_1^T v_k = 0$. And this should also be equal to 0. Because the left right hand side of the a 0. So now, $v_1^T v_2 c_2$ is the constant this come out $v_1^T v_2$ is the scalar and this will count come out. So, we one transfer v_2 is equal to 0. So, this will be 0, similarly, this will be 0 and we will get $v_1^T v_1 = 0$.

And now it has been said that the vectors are non 0. c_1 is 1 0. Therefore, c_1 is equal to 0. Similarly, we can multiply it with c_2, c_3 and c_k and so that show that the sorry, you can multiply it with v_2^T, v_3^T and v_k^T , and show that c_2 up to c_k is equal to 0. So, mutually so, this relationship will only hold when $c_1, v_1, c_2, v_2, c_k, v_k$ will only hold when c_1, c_2 is equal to 0; is the vectors are orthogonal. And

therefore, mutually orthogonal vectors are also mutually independent. This is trivial if we look into few examples. This looks very trivial.

(Refer Slide Time: 09:46)

Orthogonal vectors

The co-ordinate vectors e_1, e_2, \dots, e_n in R^n are orthogonal vectors
 e.g., in R^2 , $(1,0)$ and $(0,1)$ are orthogonal.

They form the simplest basis in R^n

Each vector e_i has a length=1. So they are called **orthonormal** basis too.

An orthogonal basis rotated by an angle θ gives another set of orthogonal basis

$(1,0)$ and $(0,1)$ are orthogonal – so are $(\cos \theta, \sin \theta)$ and $(-\sin \theta, \cos \theta)$

For example, the coordinate vectors e_1, e_2, \dots, e_n in R^n orthogonal vectors. Say we have R^2 and we have the coordinate $(1,0)$ the e_1 this is e_1 . And e_2 is equal to basically $(0,1)$ is equal to $(0,1)$. They are mutually orthogonal vectors and their also independent vectors. In R^2 $(1,0)$ and $(0,1)$ are orthogonal. They form the simplest basis. The orthogonal vectors form the simplest basis in R^n . Each vector e_i has a length of 1, like i and j , j and k they have a length of 1, and they are called orthonormal basis. A mutually orthogonal vector, if it is R^n , n mutually orthogonal vector will give us n mutually independent vectors which will be a basis.

And if these, vector have done in magnitude of 1, then we call this as a orthonormal basis. Normal is associated with dimension magnitude 1 in this case that R . And orthogonal basis rotated by an angle θ gives another set of orthogonal basis. So, $(1,0)$ and $(0,1)$ and we if we rotate them by θ like this is $(\cos \theta, \sin \theta)$, and if we rotate them by angle θ is they will be the intervect basis, basis will be rotated by angle θ , and they will be $\cos \theta, \sin \theta$ and minus $\sin \theta, \cos \theta$. So, they will be again a orthogonal basis. So, one orthonormal basis rotate orthogonal basis one orthogonal basis or orthonormal basis rotated by another. Certain angle will remain a orthogonal basis.

So, there are several orthogonal vectors like that an orthogonal vectors are independent vectors. Therefore, if we have n orthogonal vectors in R^n we should get a independent vector which will form a basis. And it is an important and useful if we can have orthogonal basis. Why because, we can very easily divide get the components of a vector along each basis decompose a vector along mutually orthogonal and mutually independent basis like we do for vectors, for vector calculus or vector algebra, when we have $a i$ plus $b j$, we can say a is component along x axis, b is component along y axis, and thing becomes very easy to handle.

(Refer Slide Time: 12:24)

Orthogonal subspaces

Two subspaces V and W of the same space R^n are orthogonal if every vector v in V is orthogonal to every vector w in W : $v^T w = 0$ for all v and w

Zero vector is orthogonal to all subspaces

In R^3 a line may be orthogonal to a line and/or a plane

A plane in R^3 cannot be orthogonal to another plane

$a \cdot a \neq 0$

Then comes the idea of orthogonal subspace. Two subspaces V and W of same space R^n are orthogonal; is every vector in v every vector small v in V is orthogonal to every vector w small w in W , or v transpose w is equal to 0 for all v ad w . So, any vector in one particular vector space is one subspace is orthogonal to a vector in another subspace. So, if we considered any vector along like the if we considered this vector and this plane and this slide, any vector along this plane is orthogonal to any vector along this line.

And now, we will tell that there orthogonal subspaces. This space is orthogonal to this subspace. So, one subspace is orthogonal to another subspace. Any vector in one subspace is perpendicular or orthogonal to any vector belong to the other subspace. And they are called orthogonal subspaces. Zero vector is orthogonal to a subspace. So, I take

dot product of 0 vector with any vector belong to any particular subspace it will be always 0. So, 0 is always orthogonal to all subspace.

In a \mathbb{R}^3 a line maybe orthogonal to a plane or a line. Like, like this line this is 3 dimensional space \mathbb{R}^3 can be orthogonal to this particular line. So, this particular line this particular lines. So, a line can be orthogonal to a line or any multiple line. And a line can be orthogonal to a plane also. So, these are orthogonal subspaces; however, and this is again interesting a plane in \mathbb{R}^3 cannot be orthogonal to another plane. Why? If we think of quickly we can think of these 2 planes, ok.

Are they orthogonal to each other? It will looks like any vector along this plane is perpendicular to any vector along this plane; however, they are not orthogonal to each other. And we can see that let us consider 2 planes in \mathbb{R}^3 , and there is at least one vector a , which is basically the common each of the planes. And this belongs to both the planes. If we take multiply dot product of this vector to itself, it is non 0.

So, plane is not orthogonal to plane. Line can be orthogonal to a plane in \mathbb{R}^3 . It is important that the ortho the dimension of the orthogonal subspaces when we add them up, like for plane that I mention is 2. So, 2 planes they have both have both of them have dimension 2. If we add them of we will get a dimension 4. It cannot be in orthogonal in \mathbb{R}^3 . In \mathbb{R}^3 the dimension of orthogonal subspace as can be added and that should be less than equal to 3. This is important you can (Refer Time: 15:34) over it will more.

(Refer Slide Time: 15:44)

Fundamental theorem of orthogonality

The row space is orthogonal to nullspace (in R^n). The column space is orthogonal to left nullspace (in R^m)

First proof: Null space is solution of $Ax=0$. So, dot product between any row of A and x is zero and they are orthogonal

$$\begin{pmatrix} a_{11} & a_{12} & \dots & a_{1n} \\ a_{21} & a_{22} & & a_{2n} \\ \vdots & & & \vdots \\ a_{m1} & a_{m2} & \dots & a_{mn} \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{pmatrix} = \begin{pmatrix} 0 \\ \vdots \\ 0 \end{pmatrix}$$

$$a_{11}x_1 + a_{12}x_2 + \dots + a_{1n}x_n = 0$$

$$a_{r1}x_1 + a_{r2}x_2 + \dots + a_{rn}x_n = 0$$

IIT KHARAGPUR | NPTEL ONLINE CERTIFICATION COURSES

And it gives the fundamental theorem of orthogonality, which says the row spaces orthogonal to null space; the column space is orthogonal to left null space. Row space and null space are in R^n and column space and left space null space are in R^m . Remember the sighted in the last class, we found out that those space is coming orthogonal to null space, and column space is coming orthogonal to left null space; however, we will try to find out the proof of this, except looking into 1 or 2 theorem. So, it is important that by 1 or 2 examples, we can verify the statement; however, the proof should be more generalized and should not be only verifiable it should be provable.

So, we will look into the proof, there are 2 proofs. The first proof is that null space is a solution of Ax is equal to 0. So, what is Ax is equal to 0? If I try to write down the Ax is equal to 0, this is $a_{11}x_1, a_{12}x_2, a_{1n}x_n, a_{21}x_1, a_{22}x_2, a_{2n}x_n$ comes up to $a_{m1}x_1, a_{m2}x_2, a_{mn}x_n$. And x_1, x_2, x_n is equal to 0. So, I can see $a_{11}x_1 + a_{12}x_2 + a_{1n}x_n$ is equal to 0. Which is basically dot product of a row, first row of A . What is it? This is $a_{11}x_1 + a_{12}x_2 + a_{1n}x_n$, dot x , dot n transpose rather transpose of this with x_1, x_2, x_n . Now transpose of this dot x sorry transpose.

This will be $a_{11}x_1 + a_{12}x_2$. So, each row multiplied with the like x vector gives us 0. Therefore, each row is orthogonal to the x vector. So, we can say that row space is orthogonal to the null space, when Ax is equal to 0; x is the solution of null space. So,

null space is the solution Ax is equal to 0. So, dot product between any row of a x is 0 and therefore, they are orthogonal.

(Refer Slide Time: 18:24)

Fundamental theorem of orthogonality

The row space is orthogonal to nullspace (in R^n). The column space is orthogonal to left nullspace (in R^m)

First proof: Null space is solution of $Ax=0$. So, dot product between any row of A and x is zero and they are orthogonal

Second proof:

If x is nullspace vector then $Ax=0$. If v is a row space vector, it is combination of rows of A : $v=A^Tz$

Now, $V^T x = (A^T z)^T x = z^T Ax = z^T 0 = 0$ - So $v \perp x$
 $\Rightarrow \text{row space} \perp \text{Nullspace}$

 IIT KHARAGPUR |  NPTEL ONLINE CERTIFICATION COURSES

The second proof is that if x is null space vector, then Ax is equal to 0. Let us see v is a row space vector. So, v can be considered as combination of rows. And v transpose v multiply A transpose which the columns and now the rows of A , A in columns of A transpose with a vector x . So, is z sorry, so, z 1 first column of A transpose plus plus z 2 first column of a transpose; is basically z 1 into first row of A plus z 2 into second row of A and so on.

. So, v is equal to a transpose z is the row space vector, because this is linear combination of the rows. Now we if we write v transpose x , which is a transpose z v is equal to x transpose z whole transpose x . In this becomes a transpose Ax by the property of transpose which is z transpose 0. And as Ax is equal to 0 z trans z transpose Ax is equal to 0 so, z transpose 0 so, this is 0. So, v is perpendicular to x so, any row space vector becomes perpendicular to the null space vector. And row space is orthogonal to null space. So, we get row space is orthogonal to null space.

So, what we got? Row space and null space both belong to R^n , dimension of row space is R dimension of null space is in minus R . So, if there are R vectors in row space, there are $m - n - r$ vectors in null space. These are vectors any of this vector in R vector is

orthogonal to $n - r$ null space vector. So, any of this vector is mutually independent with the null space vectors. So, if we have $n - r$ null space basis which are mutually independent, any of the row space which is mutually independent with that. Therefore, all R row space basis are mutually independent with the $n - r$ null space basis. So, this R and this $n - r$ gives me a total set of n mutually independent vectors, right. Rather than row space vectors are orthogonal to null space vector. Therefore, they are independent of a null space vectors.

So, each of the row space vector is mutually independent of with linearly independent with all of the null space vector. So, you get a of basis in null space, where we have $n - r$ independent vectors. And we get a basis in row space with they we have R independent vectors. So, there are R independent vectors, there $n - r$ independent vectors, and they are also mutually independent. So, you get a total set of n independent mutually independent vectors. This is in R^n ; R^n are total set of n vectors we will form the basis. So, row space and null space combining we can span the entire R^n , sorry.

(Refer Slide Time: 21:44)

Page 30/30

Orthogonality between row space and nullspace

The row space is orthogonal to nullspace (in R^n). So any vector in nullspace is orthogonal to any vector in row space. So a nullspace vector and a row space vectors are linearly independent.

$N(A)$ = null space of A , dimension $n - r$, subspace of R^n
 $C(A^T)$ = row space of A , dimension r , subspace of R^n

So, if we combine $n - r$ basis of nullspace and r basis of row space, we get n independent vectors in R^n which form a basis of entire R^n

Null space & row space combinedly span entire R^n

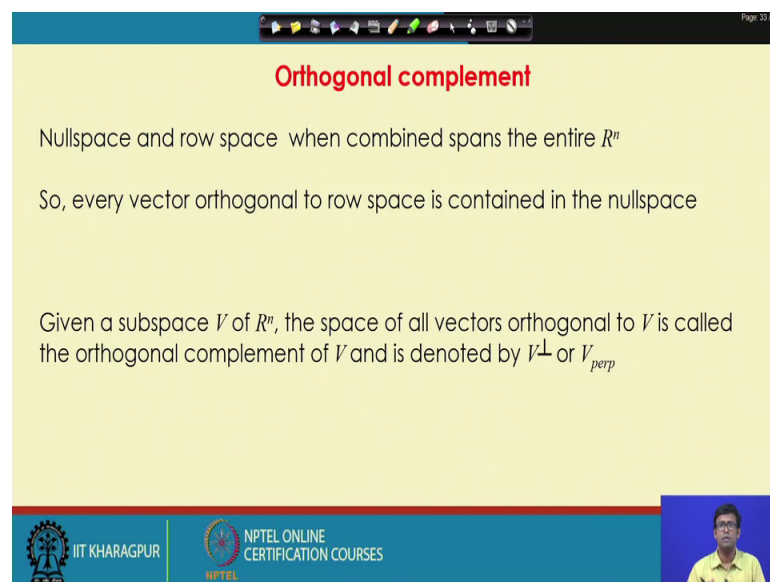

IIT KHARAGPUR | NPTEL ONLINE CERTIFICATION COURSES

So, yeah the row space is orthogonal to null space in R^n . So, any vector in null space is orthogonal to any vector in row space. So, A row space vector and the and null space vector are linearly independent. $N(A)$ is null space of A has dimension $n - r$ subspace of n . $C(A^T)$ is row space of a dimension R subspace of R^n . So, if we combine

$n - r$ basis of null space and r basis of row space, we get n independent vectors of null space and row space. And they form basis of entire \mathbb{R}^n .

So, we can also write that null space and row space combinedly span entire \mathbb{R}^n . Because basis of row space and basis of null space they are forming basis of \mathbb{R}^n . So, this meaning entire \mathbb{R}^n . So, null space so, for example, this is null space and this is row space, this span the entire \mathbb{R}^n . So, in \mathbb{R}^n in the mean vector space if there is something which is not belonging to row space that n must be in the null space. Or something which is not belonging to null space, that must be in the row space, because combinedly we get the entire space.

(Refer Slide Time: 23:26)

The slide is titled "Orthogonal complement" in red text. It contains the following text:

Nullspace and row space when combined spans the entire \mathbb{R}^n

So, every vector orthogonal to row space is contained in the nullspace

Given a subspace V of \mathbb{R}^n , the space of all vectors orthogonal to V is called the orthogonal complement of V and is denoted by V^\perp or V_{perp}

The slide also features a navigation toolbar at the top, the IIT Kharagpur and NPTEL logos at the bottom left, and a small video inset of a speaker at the bottom right.

Null space and row space when combine spans the entire \mathbb{R}^n . So, every vector, every vector orthogonal row space is contain in null space. Every vector which is not in row space is a member of null space. And given a subspace V of \mathbb{R}^n the space of all vectors of orthogonal to is call the orthogonal complement of V , and divided by V perpendicular, perpendicular sign or perpendicular. Therefore, null space becomes an orthogonal complement of row space. Whatever is orthogonal to row space, whatever does not lie in row space must be null space.

(Refer Slide Time: 24:10)

Orthogonal complement

Nullspace is orthogonal complement of row space in R^n

Left nullspace is orthogonal complement of column space in R^m

IIT KHARAGPUR | NPTEL ONLINE CERTIFICATION COURSES

And if we can write null space is orthogonal complement of row space. And similarly we can show left null space is orthogonal complement of column space.

(Refer Slide Time: 24:22)

Solution of $Ax=b$

$Ax=b$ is solvable if b lies in column space.

Left nullspace is orthogonal complement of column space in R^m . So, if any vector does not remain to column space, it will have some component in left null space.

$N(AT)$

R^m

$C(A)$

IIT KHARAGPUR | NPTEL ONLINE CERTIFICATION COURSES

So now, if we start looking into Ax is equal to b . We may last class we took an example and observe that they are the particular and null space row space column space left null space. So, started from last class row space looked into column space left null space. So, that they are perpendicular. Now in from more general sense we are coming that they are

orthogonal complement. Left null space and column space is also orthogonal complement. I am interested specifically in column space at this stage, because something which does not belong to column space now we know that they belong to left null space.

If the b vector does not belong to column space, then $Ax = b$ is not solvable. That is why I am specifically interested in column space and left null space. So, if I can say that b has a component along left null space, b is away from column space. b is not a column space vector and $Ax = b$ is not solvable. So, we will look into solution of $x = b$ from the ideas of orthogonality, orthogonal complements etcetera; $Ax = b$ solvable if b lies in column space. Left null space is orthogonal complement of column space in \mathbb{R}^n . So, if any vector does not remain to column space, it will have some component in left null space. It may be entirely in left null space or maybe combination of some use a some basis in left null space and some basis in column space may be a combination of that.

Or we can say that in \mathbb{R}^n this is the left null space and this is column space. Now, we get a vector b which is away from which is not on the column space, which comes along the column space. And it must have 2 component, one is along left column space and one is along left null space. So, if a vector b has some component along left null space, it must not be in column space. Therefore, $Ax = b$ will not be solvable; $Ax = b$ solvable when it is entirely in column space, and b does not have any component with left null space.

(Refer Slide Time: 26:38)

Solution of $Ax=b$

$Ax=b$ is solvable if b has no component in left nullspace. Or b lies in column space and is orthogonal to left nullspace.

I.e., for existence of solution of $Ax=b$:

$b^T y = 0$ whenever $A^T y = 0$

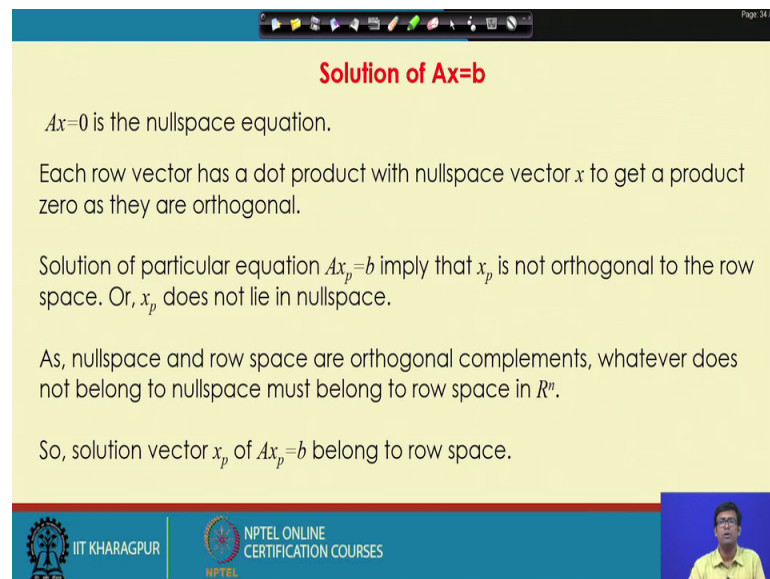

Handwritten notes:
 $b \perp y$ to $y \in N(A^T)$
Left null space eqn: $y \in N(A^T)$

IIT KHARAGPUR | NPTEL ONLINE CERTIFICATION COURSES

$Ax=b$ is solvable when b has component in left null space, or b lies in column space and is orthogonal to left null space. That is for existence of solution $Ax=b$, $b^T y = 0$, whenever $A^T y = 0$.

$b^T y = 0$ is left null space equation. And this implies that b is perpendicular to y which belongs to left null space. So, if orthogonal to left null space or $b^T y = 0$ when $A^T y = 0$, then b is orthogonal to left null space means b lies in column space. And $Ax=b$ will be solvable.

(Refer Slide Time: 27:52)

Solution of $Ax=b$

$Ax=0$ is the nullspace equation.

Each row vector has a dot product with nullspace vector x to get a product zero as they are orthogonal.

Solution of particular equation $Ax_p=b$ imply that x_p is not orthogonal to the row space. Or, x_p does not lie in nullspace.

As, nullspace and row space are orthogonal complements, whatever does not belong to nullspace must belong to row space in R^n .

So, solution vector x_p of $Ax_p=b$ belong to row space.

IIT KHARAGPUR | NPTEL ONLINE CERTIFICATION COURSES

Ax is equal to b , x is equal to 0 . So, we look into solution of Ax is equal to b further. Ax is equal to 0 is the null space solution. Each row vector has a dot product with null space vector x to get a product zero as they are orthogonal. Solution of particular equation Ax_p is equal to b imply that x_p is not orthogonal to the row space, or x_p does not lie in null space. If Ax is equal to 0 , then x has a 0 dot product with a , and x is a null space vector. Remember for particular equation is first found out particular solution, we first found out the null space equation and then did not consider the null space equation, only solve for particular solution when x_p is equal to b in case we have multiple solutions.

So, this equation x_p is equal to b says that x_p and not orthogonal. They have a non- 0 dot product. So, x_p does not lie in null space. As null space and row space are orthogonal complements, if it does not lie in null space is must lying row space. So, the solution x_p of Ax_p is equal to b belong to row space. Therefore, the solution vector always lies in the row space. Solution vector of a non-null non homogeneous equation; x_p must lie in the row space. Whatever does not trying null space in R^n must lie in the row space. Therefore, if I am when I am solving Ax is equal to b , the x I am finding that is the row space vector. That lies in the row space.

Solution of $Ax=b$

In case of unique solution nullspace is zero vector..

So, any solution of $Ax=b$, if non-zero, must lie in row space.

Therefore, if we consider the equation $Ax=b$, x is a row space vector and b is a column space vector .

So: Every matrix A transforms its row space to column space

IIT KHARAGPUR | NPTEL ONLINE CERTIFICATION COURSES

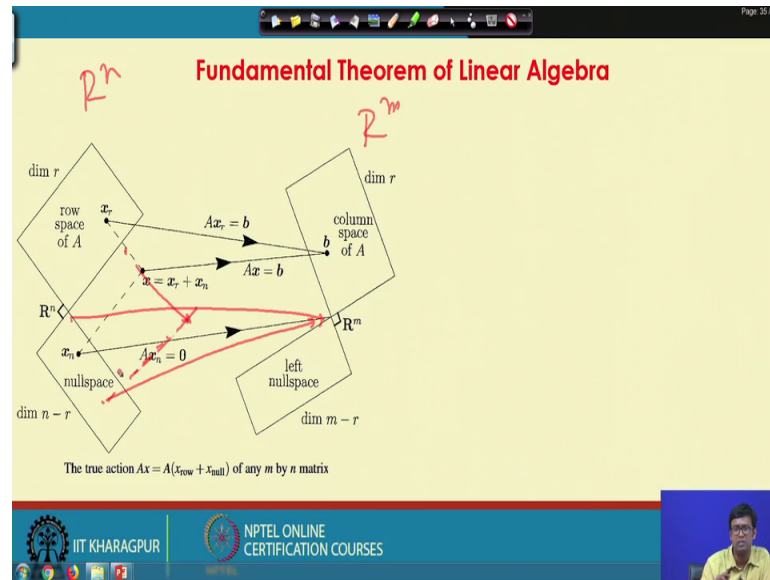

In case of unique solution null space is zero vector so, everything will lie in row space. So, any solution of Ax is equal to b if non-zero, 0 means it is both 0 is also a part of null space. But for non-homogeneous equation Ax is equal to b must give a non-zero solution. And if in case non-zero it must lie in the row space. Therefore, if we consider the equation Ax is equal to b , x , x is a row space vector, right? And b is a column space vector. So, if I multiply a row space vector by the make it is A , it will transform it to the column space vector, the product is column space vector.

And we can say every matrix a transforms it is row space to a column space vector. It is in the sense we can try that, we can take row and multiply with A and the product will be nothing but a column space vector, a combination of columns. Now, this is a this 2 or 2 few like last few discussions give us a few important one very important theorem of linear algebra, which is we call fundamental theorem of linear algebra. That is, Ax is equal to b solution x lie in the column space; lie in the row space, sorry.

The row space vector x is any row space vector let us consider multiplied with a will give me some b which is in the column space vector. Whatever does not lie in b in \mathbb{R}^n must lie in the left null space. Whatever does not lie in row space in \mathbb{R}^n must lie in the left null in the null space. And any null space vector when multiplied with the main

matrix A will give me the 0 vector. Ax is equal to 0 the null space equation. And this is pictorial representation of the fundamental theorem of linear algebra.

(Refer Slide Time: 31:40)

And I have a row space which was dimension R , which is perpendicular to a null space which is dimension n minus r . Now and there is a column space which has n dimension R , left null space as dimension n minus r . Now, I take any vector in so, the left hand side is \mathbb{R}^n and the right hand side is \mathbb{R}^m . Now I take any vector in \mathbb{R}^n which is an x vector, it has 2 component. One is along the row space; another is along the null space. The row space component when multiplied with the matrix A , we will go to the column space Ax is equal to bx .

The null space component when multiplied with A we will take us to the 0 solution. And now if we get Ax \mathbb{R} is equal to b which is in the column space. Now if I invert it, this is the mapping the row space is being map to the column space. If I invert it, column space will always have an unique mapping in the row space because, this solution is unique. The null space solution is non-unique, anything multiplied with null space can take me. So, if I have another null space vector that would have been taken me here. If I had another null space vector that would have been taken me here.

So, and based on this null space, we could have different values of x , we could have different values of x . So, outside null space if x lies outside row space, Ax is equal to b

can have infinite solution. If x is in row space the x is equal b has exactly one solution. Ax is equal to b solvable if b is in the column space. If b is away from the column space Ax is equal to b is not solvable.

Fundamental Theorem of Linear Algebra

The diagram illustrates the mapping of vectors from the row space and nullspace of a matrix A to the column space and left nullspace. The row space of A (dimension r) is a subspace of \mathbb{R}^n . The column space of A (dimension r) is a subspace of \mathbb{R}^m . The nullspace (dimension $n-r$) is a subspace of \mathbb{R}^n . The left nullspace (dimension $m-r$) is a subspace of \mathbb{R}^m . The mapping $Ax = b$ is shown as a vector x in the row space being mapped to b in the column space. The mapping $Ax = 0$ is shown as a vector x_n in the nullspace being mapped to the zero vector in the left nullspace. The total action is $Ax = A(x_{row} + x_{null}) = b + 0 = b$.

- x_r is in row space
- $Ax_r = b$ is in column space
- Every matrix maps its row space to column space and this mapping is invertible
- x_n is in null space
- $Ax_n = 0$ is zero vector
- $Ax = A(x_n + x_r) = b + 0 = b$

The true action $Ax = A(x_{row} + x_{null})$ of any m by n matrix

And x_r is in row space, Ax_r is equal to b is in the column space. Every matrix maps it is row space to column space, and this mapping is invertible. So, we can get exactly same x_r , if I invert b , if I put multiplied b with A , A inverse we will get back to x_r . However, the null space mapping is not invertible, it can take us to anywhere in the null space 0 inverse 0 can take us anywhere to the null space, x_n is in null space. Ax_n is equal to 0 is a 0 vector. And the final solution Ax is Ax_n plus x_r is equal to b plus 0 is equal to b plus 0 is equal to b .

And this is pictorial representation of the fundamental theorem of linear algebra. Now what remains in question is that incase b is not in the column space. Of course, it has no solution. But if we think from statistical point of view from a point of view of optimization, there can be something which approximately satisfies, the equation b is not in the column space, but b has a component along column space can we solve for that part. We and will look into subsequent classes, what should we do in case Ax is equal to b has no solution, b is not on column space, but b has some component in column space,

and some in left null space, what is the solution for that. So, we will we will do it in the subsequent classes.

Thank you.
