Lecture – 38
Steepest Descent Method: Algorithm and Convergence

Welcome so, we are discussing about the Steepest Descent Algorithm where we have seen that solving a problem $Ax = b$ is equivalent to find out minima of the functional $J(x)$ where $J(x)$ is defined as $\frac{1}{2}x^T Ax - x^T b$. And, in order to propose an iterative method for solving for finding the minima of $J(x)$ we discussed about the gradient such algorithm that choose any value x_0 find $J(x_0)$ there and then find out the gradient of J and move along minus gradient of J .

And move up to a certain distance where this along with J reduces on that particular line and this distance is measured by parameter α we discussed about how to find out α till which J reduces along that line. And then when you see that J has reached a local minima along that particular line change the direction and go to the another take another direction.

(Refer Slide Time: 01:20)

Exact line search for a quadratic function

$$\frac{df(\alpha)}{d\alpha} = 0$$
$$\Rightarrow v^T Ax_0 + \alpha v^T Av - v^T b = 0$$
$$\Rightarrow \alpha = \frac{v^T (b - Ax_0)}{v^T Av}$$

The diagram shows a point x_0 on a curve. A vector $v = -\nabla J$ points downwards from x_0 . A line segment of length αv is drawn from x_0 in the direction of v . The point reached is labeled as a local minima of J .

IIT KHARAGPUR | NPTEL ONLINE CERTIFICATION COURSES

So, roughly it is this particular method that start with one particular x_0 move along one direction and then see that, this is a local minima of J from here you take another direction and that is how you approach the global minima.

And this is the parameter alpha that; distance should be covered in particular one particular search direction. So, that the search is optimum and in least number of steps we reach the local minima. Now we thought about taking this into a solver and writing and proposing an algorithm for iteratively solving x is equal to b or finding J minima using this.

(Refer Slide Time: 02:15)

Formulation of steepest descent

Let x_k be the k -th iteration value, error is defined as

$$-d^k = x_k - x^*$$

where x^* is the solution: $Ax^* = b$

The residual is defined as $r_k = b - Ax_k = Ad_k$

The new iteration guess will be updated as:

$$x_{k+1} = x_k + \alpha_k \left(-\nabla J \Big|_{x=x_k} \right)$$

$b - Ax_k = b - Ax_k$
 $= b - Ax_k$
 $= A(b - Ax_k)$
 $= Ad_k$

IIT KHARAGPUR
 NPTEL ONLINE CERTIFICATION COURSES

Which is called the steepest descent algorithm let k be the k th iteration value and the error is defined as d_k is x_k minus x^* where, x^* is the solution of $Ax^* = b$, x^* is the where we have the solution x^* is equal to b that is the location where J is minima.

So, this let x^* be the point where J is minimal and d_k is the error; that means, we considered a it guess value x_k or k th iteration value x_k d_k is the error which is x_k minus x^* . The residual is defined as $b - Ax_k$, if x_k is equal to x^* we reach the right value $b - Ax$ is equal to 0.

So, residual is 0 till it is not reached this is the non 0 value and we define residual as $b - Ax_k$ or this is equal to $b - Ax_k$ why? Because $b - Ax_k$ is equal to $b - Ax_k$ minus $b - Ax^*$ because this is 0. So, this is if you d_k is equal to sorry, there is a there is a small sign convention small sign convention issue r_k is $b - Ax_k$ and this is so.

So, let us define this is equal to $x^* - x_k$ then it should come out. So, this is minus of $Ax_k - x^*$ which is $A(x_k - x^*)$. So, let us define $d_k = x_k - x^*$, new iteration guess will be updated as $x_{k+1} = x_k + \alpha_k (-\nabla J(x_k))$.

So, it started with a value of x_k and will update it to the new iteration x_{k+1} . And this is how because we are also when we are in thinking of solving $x = b$ we are also trying to find out the minima of J . So, you should go along minus grad $J(x_k)$ and we found out there is a parameter α_k by which we should go in that direction.

(Refer Slide Time: 05:09)

Formulation of steepest descent

$$J(x) = \frac{1}{2} x^T A x - x^T b$$

$$\Rightarrow \nabla J(x) = Ax - b \quad \checkmark \quad \because A \text{ is symmetric}$$

$$x_{k+1} = x_k + \alpha_k (-\nabla J|_{x=x_k})$$

$$\Rightarrow x_{k+1} = x_k + \alpha_k (b - Ax_k) \quad \checkmark$$

$$= x_k + \alpha_k r_k \quad \text{QS } r_k = b - Ax_k$$

r_k is same as the vector direction v

So: $\alpha_k = \frac{r_k^T (b - Ax_k)}{r_k^T A r_k} = \frac{r_k^T r_k}{r_k^T A r_k}$

Observation: r_k and r_{k+1} are orthogonal

Now, $\nabla J(x) = Ax - b$ so $-\nabla J(x_k) = b - Ax_k$. A is a symmetric matrix, $x_{k+1} = x_k + \alpha_k (-\nabla J(x_k))$ which is evaluated there x_k in that earlier and $-\nabla J(x_k) = b - Ax_k$.

So, $-\nabla J(x_k) = b - Ax_k$ therefore, $-\nabla J(x_k) = b - Ax_k$. So, $x_{k+1} = x_k + \alpha_k (b - Ax_k)$ and we have defined $b - Ax_k$ as r_k . So, this is $x_{k+1} = x_k + \alpha_k r_k$, r_k is the same vector as the vector direction as the same vector in the direction v r_k and v are same. It because we have written earlier $v = -\nabla J(x_k)$ now we can see that v is same as r_k .

So, I have seen that alpha is equal to v if v is minus grad J, now we have seen that minus grad J is r k. So, r k and v are same alpha is equal to v transpose b minus Ax k v transpose Av. So, we will get alpha is equal to r k transpose r k and v are same b minus Ax k by r k transpose Ar k which is r k transpose r k into r k transpose Ar k. And there is one observation which is r k and r k plus 1 are orthogonal why? Because, grad J is the direction in which J reduces first test, grad J is perpendicular to the J contour where it was evaluated.

Now, we move till J is minima or grad J this is tangential to J contour to tangential through J contour at x k plus 1 this is x k plus 1. The new direction is minus gradient of J x at x k plus 1 is perpendicular to the tangent. So, this grad J x k and grad J x k plus 1 must be perpendicular to each other. Therefore, r k and r k plus 1 are orthogonal vectors. So, nevertheless we found out that for one particular iteration how to find out alpha k?

(Refer Slide Time: 08:16)

Steepest Descent Method

1. Chose $x^{(0)}$
2. For $k=0,1,2,\dots$ Do Two matrix-vector product
3. Compute $r^{(k)} = b - Ax^{(k)}$ and two vector-vector product
4. Compute $\alpha^{(k)} = \frac{r^{(k)T} r^{(k)}}{r^{(k)T} Ar^{(k)}}$
5. Update $x^{(k+1)} = x^{(k)} + \alpha^{(k)} r^{(k)}$
6. If $|r^{(k)}| < \epsilon$ set $k=k+1$, goto 2, else iterations converged

How to reduce computational cost/ number of operations?

16

So, the steepest descent method will be start with one guess value x 0 and then do an iteration k is equal to 0 1 2 until it converges compute r r k is equal to b minus Ax k compute alpha k which is r k transpose r k by r k transpose Ar k. Update x k plus 1 is equal to x k plus alpha k r k and check if r k is less than an epsilon is a small value if the residual b minus A I have to see whether b minus ax is equal to 0 if b minus Ax is A very small value.

Then sorry if not a very small value if it is a very small value, then it is iterated if it is not a very small value. Then set k is equal to k plus 1 and go to the 2 and do the try for the convergence of the iterations.

If else if this value is very small r_k is a very small number, then you say that iterations are convergence you have reached the right solution. So, this is roughly the steepest descent algorithm what you discussed here and for a symmetric positive definite matrix, we can utilize this b irrespective of the way it has been represented as a diagonal dominant matrix or not only.

Only we have to see that this matrix is symmetric as well as positive definite, then we can utilize this method. This is in general a faster method for symmetric positive definite material this is a faster method, then up to gauss Seidel gauss Seidel SOR or Jacobi method.

However, when we look into this method, we see that if we try to think do a computer program here there are two matrix vector multiplication here A into x and A into r . So, if I have a million by million 10 to the power 6 by 10 to the power 6 matrix, each of these steps needs multiplication with each element of the matrix with the each component of the vector.

So, in a sense 10 to the power 6 into 10 to the power 6 multiplications are needed, each row needs 10 to the power 6 multiplications and they 10 to the power 6 rows.

So, this particular method needs in gauss Seidel in each iteration you only have to do one Ax multiplication because, x_i is equal to b minus sum of $a_{ij}x_j$ at the older value except the diagonal term. So, there is only one matrix vector multiplication there are two matrix vector multiplication.

So, if I try to do a computer program write a computer program out of it though the number of steps will be less than gauss Seidel; however, the calculations will be very high for large matrices. Because they are doing in each iteration the calculations will be very high for the large matrices because, they are doing lot of the Gauss Seidel is on doing only once matrix vector multiplication whereas, the steepest descent will do it twice. So, you need to modify this algorithm.

So, you seen that there are two matrix vector multiplications and two vector vector product vector vector is r^k transpose r^k and r^k transpose $A r^k$ which is in again another vector is the vector vector product.

However, they are less time consuming because if there are 10 to the power 6 rows their main only 10 to the power 6 operations are there or matrix vector is 10 to the power 6 into 10 to the power 6 10 to the power 12 operations are there is a very computer computationally costly operation if there is a matrix vector multiplication it is done twice.

So, we have to see how can we reduce the cost of the computation or number of operations, how can we improve the algorithm little bit better. So, that you can at least avoid one matrix vector multiplication here. So, that for million by million matrix 10 to the power 12 floating point operations are saved. If I can do one matrix vector multiplications here seen to look into some modifications some possible modifications into the steepest descent method before we proposed an algorithm for computer programs.

So, the idea is again if I go back to the previous slide that ah; every why I need to matrix vector multiplication one is needed to find alpha, another is needed to find r and every time we need to do one matrix multiply vector multiplication to find the updated value of r, r^k is equal to $b - Ax^k$ once we update x into row matrix vector multiplication here that is actually replaced here.

(Refer Slide Time: 13:31)

Steepest Descent Method

Updating $r^{(k+1)}$:

$$\begin{aligned} r^{(k+1)} &= b - Ax^{(k+1)} \\ &= b - A(x^k + \alpha^k r^k) \\ &= b - Ax^k - \alpha^k Ar^k \\ &= r^k - \alpha^k Ar^k \end{aligned}$$

→ also needed for computing α^k

IIT KHARAGPUR | NPTEL ONLINE CERTIFICATION COURSES

Updating r^{k+1} is equal to $r^k + \alpha^k r^k$, which is $b - Ax^{k+1}$, which is $b - Ax^k - \alpha^k Ar^k$. So, $r^{k+1} = r^k - \alpha^k Ar^k$.

And if I again go back to the previous slide Ar^k is needed also for computing of α^{k+1} . So, if r^{k+1} can be computed using Ar^k , then this is the only matrix vector multiplication which is common both to calculation of r^{k+1} as well as to the computation of α^k .

And in that light we will try to modify it will see that this is also needed for computing α^k . So, while computing α^k will store a Ar^k and you will utilize this for updating r^{k+1} .

(Refer Slide Time: 14:53)

Steepest Descent Method- Algorithm

Start with guess values of $x=x^0$

1. Compute $r=b-Ax$ and $p=Ar$
2. Until convergence, DO
3. Compute $\alpha = \frac{r^T r}{r^T p}$
4. Update $x \rightarrow x + \alpha r$
5. Update $r \rightarrow r - \alpha p$
6. Compute $p=Ar$
7. End do

until $|r| < \epsilon$

$\alpha = \frac{r^T r}{r^T (A r)}$

$r^{k+1} = r^k - \alpha^k (A r^k) = r^k - \alpha^k p^k$

A: Symmetric Positive Definite

IIT KHARAGPUR | NPTEL ONLINE CERTIFICATION COURSES

The final steepest descent algorithm method algorithm will be start with a guess value of x is equal to x_0 compute $b - Ax$ and r is equal to $b - Ax$ and define a new variable p which is Ar p will be utilized later. And until convergence; that means, convergence means that until r is less than epsilon, epsilon is a very small number do compute alpha which is $r^T r$ into $r^T p$.

So, alpha is equal to $r^T r / r^T Ar$ and now Ar has been substituted by p update x is equal to this is because the same variable x which is overwritten as x is equal to $x + \alpha r$. And that is why we written $x \rightarrow x + \alpha r$; this is a way to write something which is getting overwritten. Update x is equal to $x + \alpha r$ update r so, r^{k+1} is equal to $r^k - \alpha^k Ar$ evaluated at k th level.

So, this is $r^k - \alpha^k p^k$. So, update r is equal to $r - \alpha p$, compute p is equal to Ar and then if the convergence is not done end do means you again come back here and further with this the new value of p compute alpha update x update r and repeat this loop until you see that r is less than mod r is less than epsilon or convergence has been achieved.

So, this is the steepest descent method algorithm and this is applicable only for A symmetric what happens if A is not symmetric positive definite. Then the problem we are solving if this problem what we are solving here is not finding x is equal to b solving or J is minima. The problem we are solving is not J is minimize not now solving x is equal to

if something different is, if it is not symmetric we are solving half of A plus a transpose x is equal to b a different problem.

So, we are trying to find out minima of something which is not $Ax = b$ is solving x is equal to b . However, where convergence is based on $\|r\|$ is less than ϵ so, either it will not converge, but if it converges then it will take us to the same solution that $\|r\|$ is less than ϵ so, x is equal to b .

So, in case the matrix is not symmetric or matrix is little not the asymmetry is not very high a_{ik} is probably a_{ki} plus a small number. In that case, it still converges, but it takes a lot of many iterations does not take less number of iterations because we are not using the right solution algorithm for that cases.

However, if only the matrix is symmetric positive definite then using this method is advantageous in terms that this the formulation is complicated one, program is also probably little complicated than the Gauss Seidel method. However, this is advantageous because it sub times the number of steps are small number of iterations are small some calculations in each relation is comparable to Gauss Seidel.

So, overall computational cost is less if we apply this method, only if the matrix is symmetric positive definite, then application of this method is worthwhile. Otherwise it might give us the right result because, we are looking for this criteria that $\|r\|$ less than ϵ ; that means, $b - Ax$ is less than ϵ , we are looking into this right in here. So, it might give if it converges it will give us right it shows that it will take as the x is equal to b location.

But, it can take a very high number of iterations in the matrix is not symmetric positive definite. So, this if I have a symmetric positive definite matrix, this is the algorithm through which we will see later like Gauss Seidel have or SOR how a computer program can be developed. And we can also demonstrate that the number of iterations and as well as computational time is much small than Gauss Seidel or Jacobi or SOR method for a symmetric positive definite matrix.

So, we will see in later class that how we can develop a computer program using this and this.

(Refer Slide Time: 20:05)

Steepest Descent Method- Algorithm

Start with guess values of $x=x^0$

1. Compute $r=b-Ax$ and $p=Ar$
2. Until convergence, DO Only one matrix-vector multiplication
3. Compute $\alpha = \frac{r^T r}{r^T p}$
4. Update $x \rightarrow x + \alpha r$
5. Update $r \rightarrow r - \alpha p$
6. Compute $p=Ar$
7. End do

IIT KHARAGPUR | NPTEL ONLINE CERTIFICATION COURSES

And interestingly this is only one matrix vector multiplication earlier, we had two matrix vector multiplication. So, one has been reduced there is only one matrix vector multiplication here.

(Refer Slide Time: 20:17)

Convergence of Steepest Descent Method

Theorem for convergence:

Let A be an SPD matrix. Then A -norm of the error vectors, $d_k = x_k - x^*$, (x^* is the exact solution of $Ax=b$), generated by steepest descent algorithm satisfy the relation

$$\|d_{k+1}\|_A \leq \frac{\lambda_{\max} - \lambda_{\min}}{\lambda_{\max} + \lambda_{\min}} \|d_k\|_A$$

Handwritten: $\|d_k\|_A = d_k^T A d_k > 0$
 $\Rightarrow A$ is SPD

And this algorithm converges for any initial guess x_0 .

A -norm of E is defined as: $E^T A E$

IIT KHARAGPUR | NPTEL ONLINE CERTIFICATION COURSES

Now, we need to look into the convergence of this method that is for two d I can give you some visualization that iteratively we if we change the size direction you should approach to the J minima or this method should converge.

Now, there are there are certain theorems and analysis which can show that the error convergence means; the error will be smaller $x_k - x^*$ is smaller than is there or $x_{k-1} - x^*$ extent this error. Will finally, reduce to a very small number given certain conditions, that let a be the theorem for convergence tells that let A be and SPD matrix, that is a symmetric positive definite matrix.

Then the a norm of the error vector which is $x_k - x^*$ is the exact solution of $Ax = b$. Generated by steepest descent algorithm satisfy the relation $\|x_k - x^*\|_A \leq \rho(A)^k \|x_0 - x^*\|_A$. A norm of any vector is defined as $\|x\|_A = \sqrt{x^T A x}$.

So, $\rho(A) = \frac{\lambda_{\max}(A)}{\lambda_{\min}(A)}$ so, this is basically $\rho(A)$ I am sorry issue $\rho(A) < 1$ $\rho(A)$ norm of $\rho(A)$ or let us take $\rho(A)$ it is $\rho(A)$ norm is basically given as $\rho(A) = \frac{\lambda_{\max}(A)}{\lambda_{\min}(A)}$. This norm is satisfy the relation is less than equal to $\frac{\lambda_{\max}(A)}{\lambda_{\min}(A)}$.

So, if we have any always $\rho(A) < 1$ is less than $\rho(A)$, the error $x_k - x^*$ at any iteration is always less than the error in the previous iteration. Therefore, it should converge to a finally, this error should be a small value and it should converge to a small small number it should converge to the right solution. However, the rate of convergence here depends on not on the spectral radius rather the maximum and minimum lambda.

So, the relation the difference of the maximum eigenvalue and minimum eigenvalue of this lambda max and lambda min are there is no iteration matrix are the eigenvalues of the matrix A only. So, it depends on the eigenvalues of the matrix A. So, this algorithm and this shows that this algorithm will converge for any guess value x_0 , because this is always a number less than 1 therefore, $\rho(A)$ is always A radius always reducing.

So, finally, the error should go down it will with start with some value it will keep on the magnitude modulus of error is always reduced reducing. So, it will be a small number and this is this is a positive number right because, A is SPD this is always greater than 0, as A is SPD.

So, this number will be greater than 0 and reducing; that means, that if this is $\rho(A)$ and this is $\rho(A)$ this will asymptotically approach 0. It will never be exactly 0 it will be always greater than 0, but it will be a very small number and then it will be finally, 0. So, this algorithm will converge for any initial guess x_0 .

(Refer Slide Time: 24:07)

Convergence of Steepest Descent Method

$$\|d_{k+1}\|_A \leq \frac{\lambda_{\max} - \lambda_{\min}}{\lambda_{\max} + \lambda_{\min}} \|d_k\|_A$$

$$= \frac{\lambda_{\max} / \lambda_{\min} - 1}{\lambda_{\max} / \lambda_{\min} + 1} \|d_k\|_A$$

Spectral condition no:
 $\frac{|\lambda_{\max}|}{|\lambda_{\min}|} \geq 1$

low spectral condition no \rightarrow faster convergence.

So, the convergence rate depends on spectral condition number.

IIT KHARAGPUR | NPTEL ONLINE CERTIFICATION COURSES

This is a mistake here and this should be d_k , I should correct it in the original notes also, this is d_k . So, you can see d_{k+1} in our means $\lambda_{\max} - \lambda_{\min}$ of d_k , which is $\lambda_{\max} + \lambda_{\min}$ of d_k , which is $\lambda_{\max} / \lambda_{\min} - 1$ by $\lambda_{\max} + \lambda_{\min} + 1$ of d_k .

And spectral condition number group defined it earlier of any matrix is the ratio of λ_{\max} and λ_{\min} , now we have said that as; small as the condition number. Therefore, λ_{\max} and λ_{\min} are closer it is easier good for matrix solver. So, you are also seeing here and this is always greater than so, basically this is absolute all these are absolute values. So, this is always greater than 1, all this should be in absolute value.

So, this is always greater than equal to 1. So, as this value is close to 1, this number is smaller is 1.000 it is very small number. So, in very few steps the d_{k+1} there should approach 0. So, if convergence spectral radius is the convergence rate depends on the spectral condition number. Spectral condition number low spectral condition number; that means faster convergence.

And when discussing about condition number we have discussed that, if the condition number is small then the convergence is faster. If λ_{\max} and λ_{\min} are closed at the condition number are small convergence is faster and we can see if this number is

smaller will reach the convergence faster. So, low spectral condition number will give a faster convergence here.

So, this is the first time we discuss earlier discussed about condition number, we are seeing one example of condition number in first in the rate of convergence of the matrix particular matrix solver, which is the steepest descent method matrix solver ok.

So, this method will converge; that means, is started with some geometric functional, now we can see that once we have derived the algorithm. This algorithm converge starting with any guess value x_0 , this algorithm should take us to the convert solution of x is equal to b and that is only for symmetric positive definite matrix.

Now, the question is that the entire exercise is only devoted for symmetric positive definite matrix. A matrix may not be symmetric in reality we deal with number of cases where we get a symmetric matrices, for example, if we think of a finite difference equation that we are discussing earlier and if we use non uniform grid spacing the matrix will be asymmetric.

So, how can we modify this equation for an asymmetric matrix, as well as in a general case there can be a negative definite matrix, for positive, positive definite matrix that is a solution if the matrix is not positive definite. If there is a negative eigenvalue what is how to solve this matrix? This method does not cover those matrices. Therefore, it is still now restricted only to a closed class of method, a small class of method we use symmetric positive definite.

Now, next goal will be if we can extend this method for general matrices, which are not symmetric and non positive definite matrix. And what we will discuss for that there is called general projection methods. Instead of having a method for searching to gradients such approaching the minimum value of a functional will see a more generalized method where probably the functional is little different we are trying to find out minima of some other function. But solving a matrix which is not symmetric or which may not be positive definite also, extension of this method will take us to general projection methods, which can solve a larger class of matrices we will so, see that in the next classes.

Thank you.
