UMP Tests – I

So, far the testing procedure that we have discussed was based on the Neyman Pearson and fundamental lemma. The main assumption that we made in deriving the test procedure was that, the null hypothesis and the alternative hypothesis both were considered to be simple. And in this case when we fix the probability of type 1 error, then we were able to derive the test which is having the minimum probability of type 2 error or the maximum power and we called it the most powerful test.

However in most of the real life situations, we do not come across the simple hypothesis versus simple hypothesis problems in most of the complex situations we have composite hypothesis.

(Refer Slide Time: 01:07)

As a very simple case we may have the family of distributions as normal mu sigma square distributions, and we may like to even now we may like to test something like whether mu naught mu is equal to 0 or r mu is not equal to 0.

Note here that now this H_0 is not a simple hypothesis this is composite because σ^2 is unknown. Here we have assumed both parameters to be unknown both parameters are unknown. Therefore, these are now composite both hypotheses are composite hypothesis and therefore, the Neyman Pearson lemma does not help us to give a solution in this particular problem; that means, it does not give a most powerful test.

The simplest composite hypotheses are of this nature that we may have a one parameter family say family of distributions with one parameter θ say $f(x; \theta)$, and we may like to test about say $H_0: \theta \leq \theta_0$ against say $H_1: \theta > \theta_0$ or alternatively we may have say $H_0: \theta \geq \theta_0$ against $H_1: \theta < \theta_0$. Now let us remember our cases that some examples we considered for the Neyman Pearson lemma.

Where we had considered $\theta = \theta_0$ against $\theta = \theta_1$. I had considered 2 cases; 1 was $\theta < \theta_0$ and another was $\theta > \theta_0$. When $\theta < \theta_0$; we got a 1 sided testing region that is the rejection region that is for larger values of \bar{x} we were rejecting H_0 .

Now, in that problem in place of θ_0 suppose we replace it by another value θ_2 ; suppose we replace by another value θ_3 the testing procedure remains the same as long as this second value in the alternative hypothesis remains larger than θ_0 . In a similar way, if we are considering the reverse case $\theta > \theta_0$, then the rejection region was for smaller values of \bar{x} .

And once again if we replace this alternative hypothesis θ_0 in the same direction; that means, value which is $\leq \theta_0$ or $\geq \theta_0$, then the rejection region does not get affected. What does it mean? It means that for those values we are getting the most powerful tests; that means, this normal distribution with 1 parameter the second parameter σ^2 was considered to be known has certain property.

Now, in these situations for the changing values, we get the maximum power at each of the values this is called uniformly most powerful test. Now this family of distributions which will satisfy this property; that means, where we will get such test, it is having some particular name it is called the families with monotone likelihood ratio property.

In particular for the one sided testing of hypothesis problems like theta less than or equal to theta naught against theta greater than theta naught or theta greater than or equal to theta naught against theta less than theta naught etcetera for such cases we are actually getting the uniformly most powerful test. The results that are proved they are actually you can say they are extensions of the Neyman Pearson fundamental lemma.

So firstly, let me define this families. So, let $f(x, \theta)$ be a probability mass function or density function of a random variable say x . Let us write down the ratio $f(x, \theta_1)$ divided by $f(x, \theta_2)$ let us call this name this ratio let me call it $r(x)$ and let us take say $\theta_1 > \theta_2$. If $r(x)$ is a an increasing function of some variable say $T(x)$ then we say that the family of densities.

(Refer Slide Time: 05:59)

densities $\{f(x, \theta) : \theta \in \Omega\}$ has monotone likelihood ratios (MLR) in $(\theta, T(x))$.

Examples: 1. $X \sim N(\theta, 1)$
 $f(x, \theta) = \frac{1}{\sqrt{2\pi}} e^{-\frac{1}{2}(x-\theta)^2}$

$r(x) = \frac{f(x, \theta_1)}{f(x, \theta_2)} = e^{-\frac{1}{2}(x-\theta_1)^2 + \frac{1}{2}(x-\theta_2)^2} = e^{\frac{1}{2}(\theta_2^2 - \theta_1^2) + (\theta_1 - \theta_2)x}$
 is an increasing fn. of x ($\theta_1 > \theta_2$).

So $\{N(\theta, 1) : \theta \in \mathbb{R}\}$ has MLR in (θ, x) . $\bar{x} = \frac{1}{n} \sum x_i$

$X_1, \dots, X_n \sim N(\theta, 1)$
 The joint density $f(x_1, \dots, x_n)$ is
 $f(\underline{x}, \theta) = \frac{1}{(\sqrt{2\pi})^n} e^{-\frac{1}{2} \sum (x_i - \theta)^2} = \frac{1}{(\sqrt{2\pi})^n} e^{-\frac{1}{2} \sum x_i^2 - \frac{n\theta^2}{2} + n\bar{x}\theta}$

The word densities means it includes the probability mass functions. So, that is $f(x, \theta)$, θ belonging to the parameter space has monotone likelihood ratio, that we call MLR in $\theta, T(x)$.

Let me give an example here. Say let us consider say x following a normal distribution with mean θ and known variance 1. Let us write down the distribution $f(x, \theta)$ is $\frac{1}{\sqrt{2\pi}} e^{-\frac{1}{2}(x-\theta)^2}$. Let us consider this ratio $r(x)$ that is $f(x, \theta_1)$ divided by $f(x, \theta_2)$. Now when you write this ratio this gets cancelled out and you have e to the power minus half x minus θ_1 square plus half x minus

θ_2^2 square, that is equal to e to the power half θ_2^2 minus θ_1^2 square and then you will have plus θ_1 minus θ_2 x .

So, you can look at this, this is an increasing function. If I am taking increasing function of x , if θ_1 is greater than θ_2 because this is constant and if θ_1 is greater than θ_2 e to the power this becomes an increasing function of x . So, this family of distributions normal θ_1 , where θ belongs to real line this has monotone likelihood ratio in θ and x .

Now I have written here the distribution of 1 observation, suppose in place of x ; I have x_1, x_2, \dots, x_n suppose I have X_1, X_2, \dots, X_n . In this case $f(x, \theta)$ we have to write the joint distribution of X_1, X_2, \dots, X_n . So, the joint density of X_1, X_2, \dots, X_n . So, let me give the notation $f(x)$, here x is standing for the values x_1, x_2, \dots, x_n of capital X_1, X_2, \dots, X_n .

So, this becomes $\frac{1}{\sqrt{2\pi}}$ to the power n e to the power minus $\frac{1}{2\sigma^2} \sum x_i^2 - n\theta$ square. Let us simplify this we can write it as $\frac{1}{\sqrt{2\pi}}$ to the power n e to the power minus half $\sigma^2 \sum x_i^2 - n\theta^2$ plus $n\theta \sum x_i$. Now you have the cross product term twice $\sum x_i \theta$ with a minus sign and minus minus will become plus and 2 will cancel out. So, you get twice $n \bar{x} \theta$ where \bar{x} is the $\frac{1}{n} \sum x_i$.

(Refer Slide Time: 10:03)

$$\frac{f(x, \theta_1)}{f(x, \theta_2)} = e^{\frac{n}{2}(\theta_2^2 - \theta_1^2) + n\bar{x}(\theta_1 - \theta_2)}$$
 This is an increasing fn. of $T(x) = \bar{x}$ when $\theta_1 > \theta_2$.
 So $\{ \}$ MLR in (θ, \bar{x}) .

2. $x \sim N(0, \sigma^2)$, $\sigma^2 > 0$
 $f(x, \sigma^2) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{x^2}{2\sigma^2}}$, $x \in \mathbb{R}$

$$\frac{f(x, \sigma_1^2)}{f(x, \sigma_2^2)} = \frac{\sigma_2}{\sigma_1} e^{\frac{x^2}{2} \left(\frac{1}{\sigma_2^2} - \frac{1}{\sigma_1^2} \right)}$$

$$\uparrow \text{fn. of } x^2$$

$$\sigma_1^2 > \sigma_2^2 \Rightarrow \frac{1}{\sigma_1^2} < \frac{1}{\sigma_2^2}$$

$\{ N(0, \sigma^2) : \sigma^2 > 0 \}$ has MLR in (σ^2, x^2)

.So, now you write down this ratio $f(x|\theta_1)$ divided by $f(x|\theta_2)$ that is turning out to be. Now when you write the ratio this constant term will get cancelled out $e^{-\frac{1}{2}\sum x_i^2}$ will get cancelled out. We will be left with $e^{-\frac{n}{2}(\theta_2^2 - \theta_1^2) + n\bar{x}(\theta_1 - \theta_2)}$.

Now, this is constant, for $\theta_1 > \theta_2$ this becomes an increasing function of \bar{x} . So, this ratio and increasing function of \bar{x} is equal to \bar{x} when $\theta_1 > \theta_2$. So, this family of distributions normal θ_1 , when we are having n observations; so we have MLR in θ and \bar{x} we can say.

Now, the similar thing we can observe for various distributions let me give a couple of more examples. Here I have considered the normal distribution when the variance is assumed to be known. Now there can be other case where mean may be known and the variance may be unknown let us take that case. Let me again consider say 1 observation and then I will consider N observations generally we are dealing with the sample; so let me take this case.

Here σ^2 is a positive parameter, if we consider the density function here it is $\frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{x^2}{2\sigma^2}}$ where x is any real number. Therefore, if I consider the ratio $f(x|\sigma_1^2)$ divided by $f(x|\sigma_2^2)$. Now this will give me $\frac{\sigma_2}{\sigma_1}$ this $\frac{1}{\sqrt{2\pi}}$ will get cancelled out, $e^{-\frac{x^2}{2\sigma_1^2} + \frac{x^2}{2\sigma_2^2}}$.

Now, let us take say $\sigma_1^2 > \sigma_2^2$; that means, $\frac{\sigma_2}{\sigma_1} < 1$ is less than $\frac{\sigma_2}{\sigma_1}$. So, this term becomes positive and therefore, this is increasing function of x^2 . So, this family of normal $0, \sigma^2$ distributions, this has monotone likelihood ratio in σ^2 .

Now note here that suppose I take a sample here in place of X ; let us take sample say x_1, x_2, \dots, x_n following normal $0, \sigma^2$ and let us write the same thing once again.

(Refer Slide Time: 13:17)

Let $X_1, \dots, X_n \sim N(0, \sigma^2)$
 The joint density of X_1, \dots, X_n is $\frac{\sigma_1^2}{\sigma_2^2}$
 $f(\underline{x}, \sigma^2) = \frac{1}{(\sigma\sqrt{2\pi})^n} e^{-\frac{\sum x_i^2}{2\sigma^2}}$, $x_i \in \mathbb{R}$, $\sigma^2 > 0$
 $\frac{f(\underline{x}, \sigma_1^2)}{f(\underline{x}, \sigma_2^2)} = \left(\frac{\sigma_2}{\sigma_1}\right)^n e^{+\frac{\sum x_i^2}{2} \left(\frac{1}{\sigma_1^2} - \frac{1}{\sigma_2^2}\right)}$ $\sigma_1^2 > \sigma_2^2$
 \uparrow in $\sum x_i^2 = T(\underline{x})$
 So MLR in $(\sigma^2, \sum X_i^2)$.

The joint distribution, the joint density of X_1, X_2, \dots, X_n that will become $\frac{1}{(\sigma\sqrt{2\pi})^n} e^{-\frac{\sum x_i^2}{2\sigma^2}}$ where σ^2 is positive and each x_i is on the real line. So, when we write down the ratio, now this term gets cancelled out we will get $\left(\frac{\sigma_2}{\sigma_1}\right)^n e^{+\frac{\sum x_i^2}{2} \left(\frac{1}{\sigma_1^2} - \frac{1}{\sigma_2^2}\right)}$ where $\sigma_1^2 > \sigma_2^2$.

So, this I will put plus here. Once again you note here this is positive if $\sigma_1^2 < \sigma_2^2$ sorry if $\sigma_1^2 > \sigma_2^2$, then this term becomes positive. So, this is increasing in $\sum x_i^2$, that we will call $T(\underline{x})$. So, this family has monotone likelihood ratio in σ^2 and $\sum X_i^2$.

Now, this $T(\underline{x})$ has a special role. When we will derive the uniformly most powerful test you will see that the test will depend upon this itself. So, I will discuss a few more applications a little later let us look at the main result of this section now, that is an application of the monotone likelihood ratio property how the uniformly most powerful test exists.

(Refer Slide Time: 15:09)

Theorem (Lehmann & Romano, 2005, Rohatgi & Saleh.)

Let the r.v. X have pmf (pdf) $f(x, \theta)$ with MLR in $(\theta, T(x))$, $\theta \in \Theta \subseteq \mathbb{R}$.

(i) For testing $H_0: \theta \leq \theta_0$ against $H_1: \theta > \theta_0$, there exists a Uniformly most powerful (UMP) test, given by

$$\phi(x) = \begin{cases} 1 & \text{if } T(x) > c \\ \gamma & \text{if } T(x) = c \\ 0 & \text{if } T(x) < c \end{cases} \quad \dots (1)$$

where c & γ are determined by

$$E_{\theta_0} \phi(X) = \alpha \quad \dots (2)$$

(ii) The power function $\beta^*(\theta) = E_{\theta} \phi(X)$ is strictly increasing for all points θ for which $\alpha < \beta^*(\theta) < 1$.

So, I state the theorem. For a proper statement of this theorem you may look at the books of Lehmann and Romano 2005 or you may look at Rohatgi and Saleh books.

The proofs are also given there. So, I am not discussing the proof here. So, let us consider let the random variable X have probability mass function or probability density function say $f(x, \theta)$ with monotone likelihood ratio in θ $T(x)$. And of course, here θ is a real parameter θ belongs to say Θ which is subset of the real line.

So, the result that we are having here is that, for testing $H_0: \theta \leq \theta_0$ against $H_1: \theta > \theta_0$, there exists a uniformly most powerful test that is UMP test, given by. As before, we will use the ϕ notation for the test function. So, you reject if $T(x)$ is greater than C , you reject with probability γ if $T(x)$ is equal to C and you accept if $T(x)$ is less than C ; where C and this γ are determined by expectation of θ_0 $E_{\theta_0} \phi(X) = \alpha$, let me call this conditions 1 and 2.

Note here that similarity with Neyman Pearson lemma; in the Neyman Pearson lemma we had written f_1 by f_0 greater than k . Now if f_1 by f_0 is an increasing function of $T(x)$, then that region is transformed to $T(x)$ greater than C . So, it is as I mentioned it is direct extension of the Neyman Pearson fundamental lemma only, the result is coming from there. The power function that is we have used the notation say

beta is star theta, that is equal to expectation theta phi x is a strictly increasing for all points theta for which it lies between 0 and 1.

(Refer Slide Time: 19:05)

(iii) For all θ^* , the test determined by (1) & (2) is UMP for testing $H_0: \theta \leq \theta^*$ against $H_1: \theta > \theta^*$ at level $\alpha = \beta^*(\theta^*)$.

(iv) For any $\theta < \theta^*$, the test minimizes $\beta^*(\theta)$ among all tests satisfying (2).

Remark: If we consider the dual problem $H_0: \theta \geq \theta^*$, $H_1: \theta < \theta^*$, the inequalities in (1) get reversed.

Example: $X_1, \dots, X_n \sim P(\lambda)$, $\lambda > 0$.
 $H_0: \lambda \leq \lambda_0$
 $H_1: \lambda > \lambda_0$.

The joint pmf of X_1, \dots, X_n is

$$f(x, \lambda) = \prod_{i=1}^n \frac{e^{-\lambda} \lambda^{x_i}}{x_i!} = \frac{e^{-n\lambda} \cdot \lambda^{\sum x_i}}{\prod x_i!}$$

For all theta star the test determined by 1 and 2 is uniformly most powerful for testing H prime theta less than or equal to theta prime against k prime theta, greater than theta prime at level say alpha prime is equal to let me put a star here. This new hypothesis I am calling H naught and h 1 star at alpha star is equal to beta star of theta star. And for any theta less than theta naught, the test minimizes beta star theta among all tests satisfying the condition 2. I will skip the proof here I can look at the book of Lehmann for the detailed proof of these statements.

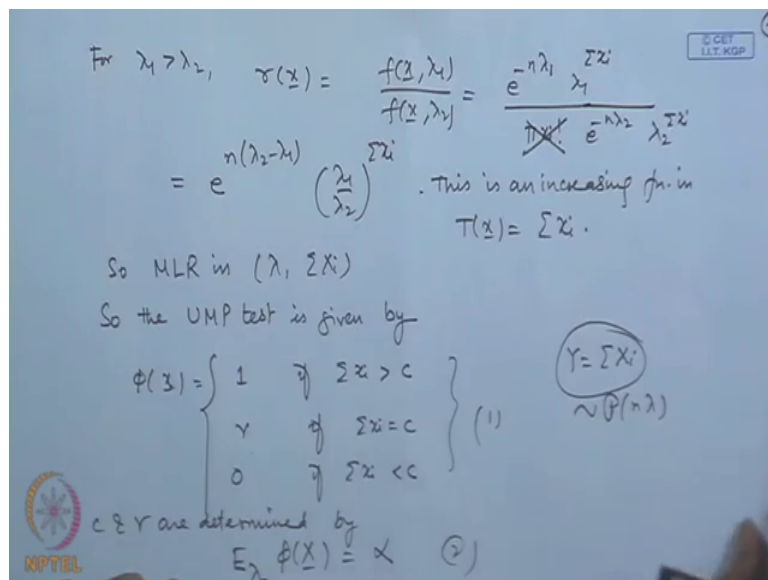

Now, one may note here I have considered theta less than or equal to theta naught against theta greater than theta naught. As I gave the heuristic argument that in the Neyman Pearson lemma and as also I gave the normal distribution example when we were testing for the mean, the rejection region for the larger value of x bar and here it is for the larger value of T x. So, if we reverse like for the null hypothesis region we consider grater and for the null alternative hypothesis we consider less than or equal to then the rejection region will also get the reverse.

So, what I just give it as a comment here. If we consider the say dual problem say H naught theta greater than or equal to theta naught against H 1 theta less than theta naught,

the inequalities in 1 get reversed. So, you have the solution in a similar manner there. Let me take an application here.

Say we have a random sample say X_1, X_2, \dots, X_n from say Poisson λ distribution. And we consider say hypothesis $\lambda \leq \lambda_0$ against $\lambda > \lambda_0$. Now let us look at this family of Poisson distributions whether it has a monotone likelihood ratio or not. So, the joint probability mass function of X_1, X_2, \dots, X_n ; So, we write it as $f(x; \lambda) = \prod_{i=1}^n \frac{e^{-\lambda} \lambda^{x_i}}{x_i!}$. That is equal to $e^{-n\lambda} \lambda^{\sum x_i} / \prod x_i!$.

(Refer Slide Time: 22:59)

So, if we consider the ratio for $\lambda_1 > \lambda_2$ let us consider the ratio $f(x; \lambda_1) / f(x; \lambda_2)$. So, it is becoming $e^{-n\lambda_1} \lambda_1^{\sum x_i} / e^{-n\lambda_2} \lambda_2^{\sum x_i}$. This λ_1 / λ_2 is greater than 1 because $\lambda_1 > \lambda_2$ therefore, this will become an increasing function, this is an increasing function in $T(x) = \sum x_i$.

So, we have monotone likelihood ratio in λ and $\sum x_i$. So, we can apply the theorem that I gave. If the family has monotone likelihood ratio in θ and $T(x)$ then for one sided null hypothesis versus one sided alternative hypothesis the uniformly most powerful test is obtained here. So, let me write it here. So, the UMP test is given by $\phi(x)$, this here x means x_1, x_2, \dots, x_n it is rejecting if $\sum x_i$ is greater than C it is rejecting with probability γ if $\sum x_i$ is equal to C it is 0 if $\sum x_i$ is less than C .

Now, the $\sum X_i$ is actually let me write say it has equal to y , then that will follow Poisson distribution $n\lambda$. Now C and γ are determined by the condition expectation of λ naught $\phi(x)$ is equal to α . Now this is reducing to let me write it as say 1 and this as 2.

(Refer Slide Time: 25:45)

The condition (2) is simplified as

$$P_{\lambda_0}(Y > c) + \gamma P_{\lambda_0}(Y = c) = \alpha, \quad Y \sim B(n, \lambda_0)$$

$\lambda_0 = 1, \quad n = 5 \quad B(5), \quad \alpha = 0.1$

So, this condition 2 let me simplify the condition 2. So, expectation of λ naught $\phi(x)$ since this $\phi(x)$ is completely dependent upon $\sum x_i$ that is y . So, it is becoming probability of Y greater than c plus γ times probability of Y is equal to c this is equal to α when the true parameter value is λ naught.

Now another point which I would like to explain here in the case of simple versus simple hypothesis, we had the probability of type 1 error as a single value. But when we have composite hypothesis for the null hypothesis, then the probability of type 1 error is a function. However, this is an increasing function which I mentioned in the statement of

the theorem also that, the power function is strictly increasing function. So, the probability of type 1 error is increasing.

So, when you are getting θ is equal to θ_0 , then at that point the maximum value is obtained. So, effectively this condition is actually the size condition, that is expectation of $\phi(x)$ equal to α λ_0 this is the maximum probability of type 1 error here, that we are fixing to be equal to α . So, the size condition now it is reduced to a condition which is really involving the distribution Poisson $n \lambda_0$. Therefore, from the tables of the Poisson distribution one can calculate this.

Suppose I say λ_0 is equal to 1 and n is equal to say 5 then basically we are looking at the tables of Poisson 5 distribution. Suppose I say α is equal to 0.1, then basically what we are seeing here is that what is the point from where. Now this C could be need not be an integer actually we may fix that thing in such a way. If it is an integer then this value may be positive if it is not integer then this may become 0.

Now, you may see from the tables that whether this randomization with probability γ is required or not. If it is not required then this probability can be taken to be 0 there will be a point where after you will have the probability α . In case that is not possible then we suitably choose a value where we a lot of probability and then we may give some value of γ also. So, now, these can be calculated from the tables of the from the tables of the Poisson distribution.

We can also see a like a binomial distribution, we suppose we have a hyper geometric distribution in all of suppose we have a negative binomial distribution in all of these distributions we may able we are able to find out the uniformly most powerful tests. I will consider this derivation of the tests in the following I will be discussing it in the next lecture.
