

Dynamic Data Assimilation
Prof. S Lakshmivarahan
School of Computer Science
Indian Institute of Technology, Madras

Lecture - 38
Basic nudging methods

In this module, we are going to be talking about another method that has been introduced way back in the early 70s called nudging. I am going to provide the basic principles of nudging and some of the associated questions relating to the design of nudging schemes. So, what is nudging? The model is always used to create a forecast, the goal of data assimilation is to make the model fit the observations. So, this fitting was done by looking at some of the square differences between the model predicted variable and the observation to decide on the values of the optimal values of the parameters. And the initial condition from which we started the model forward. And that is one of the themes that underlie 4D-var data assimilation are forward sensitivity-based data assimilation.

Nudging is an alternative method in nudging what you do you compute the forecast error, which is the difference between the model predicted observation and the actual observation. This error in the forecast is often used as the forcing, the forcing that makes the model move towards the observation, this ability to force the model by adding a force that depends on the forecast error is the fundamental idea behind the nudging scheme. So, to nudge to be able to force to be able to steer the model towards the observation. These words force nudge steer essentially captures the fundamental principle that underlie this notion of nudging algorithms or nudging methods.

(Refer Slide Time: 02:27)

EARLY HISTORY

- Anthes (1974) introduced the nudging method-Initialization of Hurricane prediction Model – (JAS, vol 31, PP 702-719)
- Hoke and Anthes (1976) – Dynamic Initialization methods (MWR (1976) PP 1551-1556)
- Idea: Use the model forecast error to force the model to reduce the over all forecast error

2

A bit about a early history, Anthes in 1974 introduced the nudging method. He used this for initialization of hurricane prediction model, it was published in general atmosphere sciences in 1974. Hoke and Anthes in 1976 further explored the use of nudging schemes. Again, within the context of hurricane forecast, and that paper was giant paper was published in 1976. In monthly with the review the idea is to use the model for the model forecast error to force the model. So, as to reduce the forecast error. So, it is a kind of a feedback principle. So, the model makes a forecast observations are there is a forecast error, I am using the forecast error to be able to force the model to be able to reduce the forecast error. This is the fundamental principle that underlie any feedback control mechanism. So, it is a kind of a feedback control theory; that is, brought to focus by this nudging scheme within the context of data assimilation methodologies.

(Refer Slide Time: 03:54)

NUDGING SCHEME

- Let $x_k \in \mathbb{R}^n$ and $M: \mathbb{R}^n \rightarrow \mathbb{R}^n$
- Forecast model (deterministic)
$$x_{k+1} = M(x_k), \text{ with } x_0 \text{ as I.C.} \rightarrow (1)$$
- Let $Z_k = h(\bar{x}_k) + V_k \rightarrow (2)$
be the observations where $Z_k \in \mathbb{R}^m$ and $h: \mathbb{R}^n \rightarrow \mathbb{R}^m$
- \bar{x}_k is the true state of the system that the model in (1) tries to capture
- $V_k \sim N(0, R_k)$ is the observation noise

3

So, did it to get a feel for this nudging scheme. Let us consider a state, x_k at a time k which is an \mathbb{R}^n . M is a map from \mathbb{R}^n to \mathbb{R}^n the forecast model I am assuming to be deterministic with x_0 as the initial condition. The observations are again non-linear function of the state \bar{x}_k be the true state of the system that is not known I only have information about the true state through the observation. V_k s are the observation noise, h is the forward operator. Again, I would like to emphasize the notion of a true state. And the observation noise is discussed here, it is a standard set up. So, what is the difference between this and the cognate filtering scheme? The model is deterministic.

So, this has commonality with 4DVAR the early in the early 70s within the meteorological literature. They consider the model to be a perfect. So, under the perfect model assumption noise is the observation. They would like to be able to use the forecast error to force the model which will in turn make the model move towards the observation.

(Refer Slide Time: 05:18)

NUDGING SCHEME

- Let $\bar{M}: \mathbb{R}^n \rightarrow \mathbb{R}^n$ and

$$\bar{x}_{k+1} = \bar{M}(\bar{x}_k), \text{ with } \bar{x}_0 \text{ as the I.C.} \quad \rightarrow (3)$$

be the true unknown deterministic system being modeled.

- $\tilde{M}(x) = M(x) - \bar{M}(x)$ - model error

- $\tilde{x}(0) = x(0) - \bar{x}(0)$ - error in I.C

- Forecast error:

$$e_k = z_k - h(x_k) \quad \rightarrow (4)$$

So, let \bar{M} be the true model dynamics. So, we are now going to develop a general theory. Let \bar{M} be the true model dynamics. \bar{x}_{k+1} is equal to $\bar{M}(\bar{x}_k)$ with \bar{x}_0 as the initial condition be the true unknown deterministic system being modeled.

If \bar{M} is equal to M , the model is perfect. If \bar{M} is different from M the model has an error. So, I am now going to consider a generalization of the nudging scheme, where I am going to think that the model may or may not be perfect. So, let $\tilde{M}(x)$ be the model error. $\tilde{M}(x)$ is equal to $M(x) - \bar{M}(x)$ that is the model error. $\tilde{x}(0)$ is equal to $x(0) - \bar{x}(0)$ is the error on initial condition. So, if I use M as the model to be able to generate the forecast x_k . x_k is the forecast generated out of the model M , M may have errors z_k is the observation, coming from measurements in the real world. So, e_k is the forecast error as given in 4.

(Refer Slide Time: 06:54)

NUDGING SCHEME

- Define

$$\underline{x_{k+1}} = M(\underline{x_k}) + \underline{Ge_k} \rightarrow (5)$$

with x_0 as the I.C - the nudged dynamics.

- $G \in \mathbb{R}^{n \times m}$ is a gain matrix
- Ge_k is the artificial forcing applied to the forecast model in (1)
- The error term e_k in (5) represents state feedback

$$e_k = z_k - h(y_k)$$

Now, what is the nudging scheme? Consider an otherwise deterministic model x_{k+1} is equal to M of x_k , please understand x_k is the forecast starting from x_0 on the model M . M may have errors the initial conditions may have errors. So, the forecast x_k generated or the model equation may have errors. I would like to be able to add a forcing term. Please remember, e_k is a forecast error G is a matrix. So, G times e_k is the forcing that is artificially added to the model. The forcing always makes the solution move towards a particular goal. Our aim is to be able to find G such that asymptotically the model state moves towards the observation. Which represents the true state of the model.

So, G is called a gain matrix G is called the gain matrix. G is again an n by m matrix. G of e_k is a vector. There is an artificial forcing applied to the forecast model. The error term e_k represents a state feedback. Why? Please remember e_k is equal to z_k minus h of x_k . Therefore, I am using the state information to force the model. So, that is what is called the state feedback.

(Refer Slide Time: 08:42)

EARLY APPROACHES (1974 – 1990)

- The idea of state feedback has been around since the days of steam engines
- The gain matrix G was empirically designed
- The model response to external forcing depends on the intrinsic relaxation times of the model
- Design of G was essentially based on time scale considerations
- Nudging scheme in (5) has a strong similarity to the "design of observers" developed during the early 1960's in control theory (Luenberger (1964))

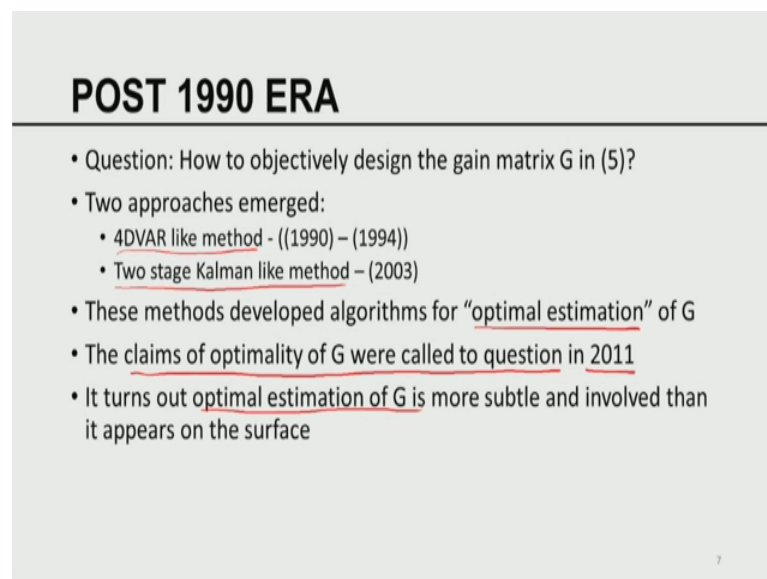

The idea of the state feedback has been around since the day since the early days of steam engines. The gain matrix G in the early days was empirically designed, I am now talking about some of the early approaches to design of nudging scheme the early approaches period from 1974 to 1990. During this period several people have applied nudging schemes to be able to make data assimilation schemes in other words you are trying to use the data to force. The model are the forecast error which involves data towards the model.

So, the model response to external forcing depends on the intrinsic relaxation times of the model. So, what is the basic idea? $G e_k$ is the forcing to the model. If you apply a force to a dynamic model, how long does it take for the model to respond to the initial force? That is that depends on what is called the relaxation times. The intrinsic relaxation times in engineering, we also call it time constants. So, the design of G in the early days was essentially based on the time scale considerations. What is the intrinsic time scale of the processes involved? How long does it take for the model to respond to the external force? So, the value of the matrix G was essentially heuristically decided, and considerations was essentially based on the time scales of the processes involved in in the model solution.

So, the nudging scheme in 5 has a strong similarity to the design of observers. The theory of the design of observers in in in control theory. The theory observers was developed

earlier in by Luenberger in 1964. It is not very clear whether Anthes and his group knew about this work on Luenbergers. Luenbergers work on observers, but the observing observer-based design as well as the nudging schemes had a very strong similarity structurally. So now, you can see Kalman filters came from control theory the notion of observers was already in existence in the early 60's in control theory, and maybe it was invented independently by anthes. But I would like to emphasize a very strong similarity between the nudging scheme as used in geophysical literature as well as the observer designs in in control theory.

(Refer Slide Time: 11:48)

POST 1990 ERA

- Question: How to objectively design the gain matrix G in (5)?
- Two approaches emerged:
 - 4DVAR like method - ((1990) – (1994))
 - Two stage Kalman like method – (2003)
- These methods developed algorithms for “optimal estimation” of G
- The claims of optimality of G were called to question in 2011
- It turns out optimal estimation of G is more subtle and involved than it appears on the surface

So, you can see there is a great influence of control theory in the design of data assimilation algorithms. So now, I am going to talk about the post 1990 era. What is the question? How to object so, before mainly people were heuristically designing values of the gain matrix G to be able to force the model towards the model state towards the observation so as to reduce the error. The only consideration they used was based on relaxation time. And that is all, but in many cases, it worked very well. But as the theory of 4DVAR was well developed, as the theory of optimal methodology was very well understood, the notion of being able to estimate the optimal state and the and the theory behind the strong constraint formulation we constrained formulation was well understood. Around the turn of 1990 the emphasis shifted towards trying to objectively design the gain matrix. That essentially dictates the amount of forcing that that was applied to the model equations.

So, 2 approaches emerged within this quest for optimal approach to the design of the gain matrix. One is the 4DVAR like methods. One is the 4DVAR like methods. Another is the 2 stage Kalman filter like methods. The 4DVAR methods sprang up in the early 1990 to 1994. The 2 stage Kalman like method arrows around was announced around 2003. These methods developed algorithms for optimal estimation for G. So, what did they do? Well, G is the known and they wanted to be able to optimally estimate the appropriate value of G. So, they brought the full force of least square based estimation theory within the framework of 4DVAR are within this within the framework of 2 stage Kalman like methods.

In 20 even though these theories were known in 2011, it was pointed out there are certain the claims of optimality that are obtained by these researchers were found to be a little defective. It turns out the optimal estimation of G is more subtle and involved then it appears in the surface, when you read the papers on 4D like 4DVAR like methods as well as 2 stage Kalman like methods. We are going to talk about both the methods as well as some of the problems associated with the methods, and ways to go around some of these challenges.

(Refer Slide Time: 14:55)

4DVAR BASED METHOD

- Stauffer and Seaman (1990), Stauffer and Bao (1993), Zou, Navon and Le. Dimet (1992)
- Referring to (4), let

$e_1, e_2, \dots, e_N \rightarrow (6)$

be known forecast errors at k times $1 \leq k \leq N$
- Define

$J_2(G) = \frac{1}{2} \sum_{k=1}^N \langle e_k, R_k^{-1} e_k \rangle \rightarrow (7)$

weighted sum of squared forecast errors

\downarrow
 $J(x_0) - 4DVAR$
 $J(G) - NVDING$

So, 4DVAR based methods. Stauffer and seaman Stauffer and Bao, Zou, Navon and Le Dimet were some of the earliest people who were working in trying to find the optimal value of G. So, referring to the equation 4 referring to the equation 4 let me go back.

Equation 4 at the bottom of slide 4 is the forecast error of the non-linear model. So, 4DVAR based methods were introduced by at least 3 sets of authors Stauffer and Seaman, Stauffer and Bao, Zou, Navon and Le Dimet in the early 90's. Referring to 4 which refers to the expression for the forecast error.

Let e_1, e_2, \dots, e_n be the set of forecast errors created by the model forecast are based on the model forecast. So, in other words, you can see like the 4DVAR like scheme here. So, while the original nudging scheme, involves essentially adding a forcing to the model and let the model evolve these people coming from the 4DVAR methodology. Their aim is to be able to design the optimal G . So, they are doing an offline experiment. What is the goal of this offline experiment? Let us pretend that there are n observations. If there are n observation then there are n forecast errors. If there are n forecast errors, then I can compute the least square cost function J_2 of G which is given by $\sum_{k=1}^n e_k^T R_k^{-1} e_k$. I am sorry the inner product of e_k with $R_k^{-1} e_k$.

What is this? This is the weight of sum of squared errors. Please understand this is exactly the cost function that is used to minimize to find the optimal initial conditions and parameters in 4DVAR as well as forward sensitive based method. You can see the approach because 4DVAR is something they know very well. And they were they were part of the development of the 4DVAR techniques. So, they would like to look at this scheme, as though it were a 4DVAR scheme to be able to estimate G . Another difference is that in the classical 4DVAR they use this kinds of objective function to decide the optimal initial condition. In the nudging I am not going to worry about where they the model starts. Initially the model may have forecast errors, but as time goes on adding $G e_k$ forcing to the model will try to correct the model forecast errors, while the model is an evolution. So, that is the basic idea.

In the 4DVAR we wanted to be able to start from the initial optimal initial condition so that starting from the initial condition, the new forecast generator will match the observation as much as possible. Here that is not the goal. Initial condition could be anything. Our aim is to be able to simply move the model towards the observation as the model starts operating. So, they were able to understand that I may not want, I may not be able to correct some of the initial forecast errors, but in time the feature errors may go to 0. R may become very small, that is the idea. So, you can see in the 4DVAR the J_2

function was a function of if you if you recall we call it function of $J \times$ naught that is in 4DVAR.

In here we calling it J of G in nudging. So, the independent variable with respect to which 4DVAR was with respect to which the minimization was done is the initial condition. The independent variable with respect to which the minimization is going to be done in the optimal design of nudging matrices is G . The elements the metric them self G that is essentially. The difference, but rest of it are very similar. So, mathematics is not too different from what 4DVAR involves.

(Refer Slide Time: 19:33)

PRIOR INFORMATION ON G

- Let \hat{G} be the prior estimate of G obtained through empirical considerations relating to relaxation times of the model
- Define a penalty term

$$J_p(G) = \frac{\beta}{2} \|G - \hat{G}\|_F^2 \quad \rightarrow (8)$$

where

$$\|A\|_F^2 = \sum_{i=1}^n \sum_{j=1}^m a_{ij}^2 \quad \rightarrow (9)$$

called the Frobenius norm
- The constant $\beta > 0$ is a large penalty constant and is given

$\|A\|_F = \left[\sum_{i,j} a_{ij}^2 \right]^{1/2}$

Again, they wanted to bring in the notion of background. Why this notion of background is useful? Because in the pre-90 era they have been very successful in trying to demonstrate the usefulness of nudging scheme based on some empirical values of G . So, that is the knowledge they knew what reasonably well in many circumstances. So, they do not want to throw that knowledge out of the window; say, they would like to be able to use some of the prior knowledge where nudging had worked. So, they would like to be able to give the benefit of doubt.

So, they said let \hat{G} be the prior estimate of G obtained through empirical consideration relating to the relaxation times of the model. So, quite a lot of time scale analysis of the models have been done. So, they know which time scales respond to what type of forcing. And that knowledge they didn't want to go as a waste. So, they assume

well we will also want to take advantage of some of the earlier estimates. So, let \hat{G} be a prior information. So, you can see now they are combining a prior and the new information coming from the forecast errors, they would like to be able to combine the 2 types of objective functions. So, the prior term gives rise to what is called a penalty term, a penalty term is as follows. The penalty of G is $\|G - \hat{G}\|_F^2$ times β over 2. It is the square of the Frobenius norm. You may recall from our example from our module on matrices the Frobenius norm square. I am sorry, I will simply say the Frobenius norm.

So, the Frobenius norm by definition is equal to the sum of a_{ij}^2 sum is over i and j . It is something like the Euclidean norm. I simply take the sum of all squares of all the elements of the object if it is a vector. That is one sort of object if it is matrices that is another set of objects. So, it is simply sums of squares and the square root of that. So, that is called the Frobenius norm. So, the penalty term regards is related to the difference between the 2. So, what does it mean? I would like so, what is the penalty term telling you? I am interested in designing an optimal G , I know they have been using \bar{G} , but \bar{G} I am sorry, \hat{G} the \hat{G} was obtained from heuristic consideration. I am trying to design G optimally. I am trying to design G optimally based on the forecast sums of forecast errors. At the same time, I do not want my G to be far removed from \bar{G} , because \bar{G} already worked.

So, it is a so, I want to find an optimal G . That is a compromise between minimizing the sums of forecast errors. At the same time going not too far away from \bar{G} I am sorry \hat{G} . So, we have defined the Frobenius norm in here. So, the constant β is called the penalty parameter. If the constant β is large, since I am going to minimize the product has to be small. So, if β is large G will be much closer to \hat{G} . If β is small, I am trying to relax the distance between G and \hat{G} . So, by looking by essentially picking the value of β , one can have a variety of different range of G with respect to \hat{G} . In other words, I have \hat{G} here. Do I want my G to be in a sphere of radius dictated by the value of β ?

So, if β is small. It will be you have more freedom for G . If β is very large, because if β is large and the norm is large, it will it will it will not come to minimum. So, if β is large the only way to minimize it is to force G towards \hat{G} . So, that $\|G - \hat{G}\|_F^2$ will be much smaller. So, that is the idea of the penalty term. So, you have 2 terms now. One I do not want my new estimate to be too far away from the old estimate that

they have used based on heuristic consideration. I do not I am, and I am doing myself some freedom by being able to choose the penalty term.

(Refer Slide Time: 24:31)

OPTIMIZATION PROBLEM

- Define

$$Q_1(G) = J_2(G) + J_p(G) \rightarrow (10)$$
- Compute the matrix G that minimizes $Q_1(G)$ using the nudged model dynamics in (5) as a strong constraint.
- This can be solved using the first order adjoint method developed in Module 5.1
- Recall that adjoint method provides $\nabla_G Q_1(G)$ which is then used in a minimization algorithm until convergence – see Module 4.3

At the same time, I have the forecast error term sums of square errors. Therefore, I am not going to consider up a new criterion which is $Q_1(G)$ which is going to be a sum of J_2 plus J_p .

Why I call it J_2 ? Because it is it isn't 2 norm. J_p , p for penalty term. So, compute the matrix G that minimizes $Q_1(G)$, where the nudge dynamics is going to be used as a strong constraint. Please understand, that that the nudge dynamics is the one that is going to be ultimately used in the forecast. So, then I cannot decide G are minimize this independently I have to find an optimal G within the context of the dynamic models. Therefore, it is formulated as a strong constraint problem. So, we have we have now essentially formulated the problem. So, what is that we can do we can essentially develop the first order adjoint method. That was developed in 5.1. So, we can use the first joint a first order adjoint method of module 5.1 to be able to decide on the optimal G and the optimal G . So, what is that we do, we start from we start with the G , run the model forward in time. Compute the forecast errors. Compute the objective function. And evaluate the gradient of the objective function. And then once you evaluate the gradient of the objective function numerically, I can use it in a gradient method.

So, as to minimize the elements of so, as to minimize the objective function $Q \approx G$. Recall that adjoint method gives rise to the gradient. Which is then used in some minimization algorithm until convergence. And we have already talked about minimization algorithms in module 4.3. So, by because we have done lot of things relating to adjoint methods relating to optimization methods. Our discussion becomes simpler, because we do not want to repeat the entire derivation. An interest reader can simply apply. The methods and derived the up, and derive the expression for the gradient. So, this was the theme of people who wanted to be able to estimate G optimally using 4DVAR like method.

(Refer Slide Time: 27:12)

CHALLENGES

- Two problems arise
- First: Getting the prior value \hat{G} is often difficult
- To appreciate the second and a more serious problem, rewrite (5) using (2) as follows:

$$x_{k+1} = [M(x_k) + G(h(\bar{x}_k) - h(x_k))] + Gv_k \rightarrow (11)$$

x_1
 x_2
 x_3
 x_4

$\text{DET.} \rightarrow$ RANDOM

$x_{k+1} = M(x_k) + G e_k$
 $e_k = \bar{z}_k - h(x_k)$
 $\bar{z}_k = h(\bar{x}_k) + v_k$

- This is a first order nonlinear autoregressive process
- This implies that the forecast and hence the forecast errors are serially correlated

$x_k - \text{random}$ $x_k - \text{Serially correlated}$

11

But there are a couple of philosophical challenges. What is the first one? Getting the prior value of G hat may not be as simple as one deems with why is that. If you change the model if we change the process for hurricane prediction the dynamics is of one type where the time scales are of one time. If you change the model equation and go from hurricane to other physical processes, again the time scale analysis will be different. Therefore, the choice of G hat depends very much on the process that is to be used are the process that is captured by the model. So, in general there are no specific guidelines for choosing G hat. So, the only thing that we can fall back on is that for those processes for which nudging method have applied in the early years.

You have a very, very well-defined \hat{G} , but in general there is no clear-cut algorithm for generating \hat{G} . So, the difficulty with respect to getting the prior value is one problem. To appreciate the second difficulty, and this is a more serious problem, we want to be able to write 5 using 2 as follows. So, let us go back to 5 and 2 what they are. So, 5 is the nudged dynamics, 5 is the nudged dynamics. And 2 is the observation equation. So, I am you know going to combine the 2 to be able to come up with the exact equation for the nudged dynamics. So, when I use when I use 2 and 5, they explicit equation for the nudged model becomes this. Why where is this coming from? Please understand, x_{k+1} is equal to M of x_k plus G times e_k . And e_k is equal to z_k minus I am sorry, z_k minus $h^T x_k$ and z_k is equal to $h^T \bar{x}_k$ plus V_k .

So, these are all the various quantities that are involved in here. So, z_k is equal to $h^T \bar{x}_k$ plus V_k \bar{x}_k is the unknown true state. So, I substitute z_k in here I get e_k , I substitute e_k in here. If you do these substitutions the resulting equation takes this form. So now, let us look at the structure of this it consists of a deterministic component. Why this is deterministic component? M of x_k is that M of x_k is a deterministic model forecast, $h^T \bar{x}_k$ the 2 state that is a deterministic. $h^T \bar{x}_k$ that is the forecast an observation counterpart of the observation. So, this term $h^T \bar{x}_k$ minus $h^T x_k$ is there is the actual expression for the forecast error true minus the actual G is a multiplier constant. So, this term is essentially a deterministic term.

The V_k term now occurs as $G V_k$. So, that is the random term. So, nudging method in fact, induces a stochastic dynamics, because observations are stochastic. Even though you are model your model is deterministic, the process is stochastic because of the observation always have observation noise. If you look at this carefully, you can readily see this is the first order non-linear autoregressive process. So, what does it mean? x_k is not deterministic x_k is stochastic. So, in the previous approach to 4DVAR they didn't realize that that is the stochastic term that is affecting the evolution they simply assume that there is no such thing as a stochastic part in the forcing, they applied the 4D 4DVAR like scheme. And they found optimal within the framework what they had built. But a clear examination of that of those ideas essentially it tells you, a correct formulation has to take into account this autoregressive process. Why this is autoregressive? x depends on the x_{k+1} depends on the previous x_k . So, what is an autoregressive process, this is $k+1$, this is k .

So, x_k plus 1 depends on the previous values of the state. So, I am dependent on myself at the previous time plus a random noise, plus the random noise. So, once you recognize this is an autoregressive process x_k becomes a random. If x_k is random what does it mean? x_k the trajectory is a random process. So, this essentially tells you x_k s are serially correlated, x_k serially correlated. Why they are serially correlated? Let us go back now. I have x naught I have x_1 . x_1 has the effect of effect of then x_2 x_3 . x_3 x_3 depends on x_2 . x_2 depends on x_1 . x_1 is random x_2 is random. Therefore, x_1 and x_2 are not totally independent they are x_1 is a random process R , R is a realization of random process x to the realization of random process x_2 depends on x_1 . So, there is a serial correlation that is induced.

So, this serial correlation was neglected in almost all of the treatment of nudging schemes. And this observation was first made by us. So, we would like to be able to make amendments to the optimal estimation of G by taking this serial correlation into account. So, that is one of the second problem. Not only second problem, but also, we propose a solution to go around and solve the second problem.

(Refer Slide Time: 34:32)

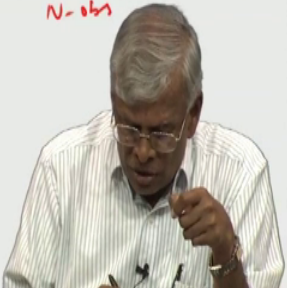

A CORRECTION TERM

- Let $e_k : 1 \leq k \leq N$ be the correlated forecast error sequence
- Define a matrix $C \in \mathbb{R}^{Nm \times Nm}$ such that

$C_{ij} = \text{Cov}(e_i, e_j) \quad \rightarrow (12)$
- Define $e(1:N) = (e_1^T, e_2^T, \dots, e_N^T)^T \in \mathbb{R}^{Nm}$
- Define

$J_3(G) = \frac{1}{2} \langle e^T(1:N), C^{-1}e(1:N) \rangle \rightarrow (13)$

$R^{Nm \times Nm}$
 $e_k \in \mathbb{R}^m$
 $N = \text{obs}$

So, let us let us talk about this now. So now, that we have established that the errors are serially correlated. So, what did I want? I would like to be able to define a matrix C . What is this matrix C ? The matrix C is $R N m$ times $R N m$. Why $N m$? M is the size of the forecast error. Please understand, please recall this decides the forecast error. I have

N observations. So, if I consider all the observations to all the observations together as well as I consider a gigantic vector. The set of all forecast errors from time 1 to n. I am sticking them all together to get a gigantic vector which is $R \times n \times m$.

If I have a vector $R \times N \times m$, its covariance must be $R \times N \times m$ times $R \times n \times m$. So, C is the represents in M a gigantic matrix that represent the serial correlation between all the all the states. So now, we are going to define in now you may ask a question, how do you know C. We have to estimate C, because once we know that they are serially correlated we have to take that correlation to account in trying to define your weight function. And that is what $J_3(G)$ is all about. So, $J_3(G)$ is an alternative to $J_2(G)$ that we saw earlier, $J_2(G)$ neglects the serial correlation. Now this is a new objective function, that involves the weighted sum of squared errors, the weighting is related to the serial correlation matrix.

(Refer Slide Time: 36:39)

A CORRECT FORMULATION

- Define

$$Q_2(G) = J_3(G) + J_p(G) \quad \rightarrow (14)$$
- Minimize $Q_2(G)$ using the nudged dynamics in (5) as the strong constraint
- Computing the covariance matrix C in (12) is very difficult
- Hence finding optimal G for nonlinear model is very difficult
- The so called optimal methods are not optimal

13

So now we can minimize, now we can minimize with respect to a new function instead of Q_1 is Q_2 $Q_2(G)$ is equal to $J_3(G)$ plus $J_p(G)$ if you minimize $J_2(G)$ using the nudge dynamics as a strong constraint model. You try to take into account the serial correlation, but computing the covariance C in 12 is not easy.

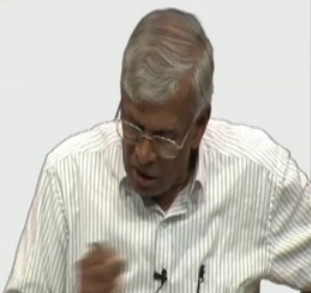

Hence in principle finding an optimal G for non-linear model is a difficult problem. So, in our view the so called optimal methods that are proposed between 1990 and about 2005. Covering a period of about 15 years. They claim that their optimal is indeed are not optimal. So, that is that critique about the methodology. And we are also going to

suggest a way out of this critique, but in general. So, what is that mean? Nudging you can implement heuristically. More often that did not works, but if you want to move away from heuristic methodology to an optimal methodology, where I am trying to design a G which is best, then you have to take into account all the processes that are involved. If you look at it carefully, there is a serial correlation trying to minimize the errors without taking that serial correlation to an account always leads to results that are not optimal. That is the, that is it that that is their simple way of looking at what is happening in here.

(Refer Slide Time: 38:12)

STRUCTURE OF FORECAST ERRORS

- True dynamics: $\bar{x}_{k+1} = \bar{M}\bar{x}_k, \bar{x}_0 - I.C \rightarrow (15)$
- Iterating: $\bar{x}_k = \bar{M}^k \bar{x}_0 \rightarrow (16)$
- Observation: $Z_k = H\bar{x}_k + V_k, V_k \sim N(0, R)$
 $= H\bar{M}^k \bar{x}_0 + V_k \rightarrow (17)$

So, in order to be able to define the matrix e I have to look at the structure of the forecast errors, because if you want to be able to understand the serial correlation I need to understand the structure of the forecast errors. So, let us spend few minutes on trying to understand the structure of the forecast errors, within the context of being able to consider the nudging scheme as the first order non-linear autoregressive process. That is the next step. So, let this be the true model. Let \bar{x} not bar be the true, but unknown initial state. So, what does it mean if you use the true model, and starting from the true initial state the model forecast will be perfect? It will match the observation modulo noise. Please understand, when we say match, match only the deterministic sense, we cannot match the random process anytime. So, whenever we say something matches something, it is always modulo noise. Mod noise is something we may have to live with. So, if I iterate this equation \bar{x}_k is equal to $\bar{M}^k \bar{x}_0$. So,

observation is given by this equation. So, I can substitute 16 in here to get 17. So, the expression for z_k the observation at time k is given by equation 17.

(Refer Slide Time: 39:51)

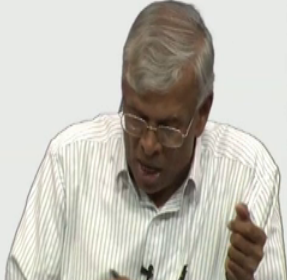

NUDGED FORECAST MODEL

- $x_1 = Mx_0, x_0 - \text{I.C} \rightarrow (18)$
- For $k > 1$: $x_{k+1} = Mx_k + G(Z_k - Hx_k)$
 $= Ax_k + GZ_k \rightarrow (19)$
- $A = M - GH$
- Iterating (19):

$$x_k = A^{k-1}x_1 + \sum_{j=0}^{k-2} A^j G Z_{k-1-j} \rightarrow (20)$$

LINEAR - MODEL

- OBS

So, x_1 is equal to M of x naught, sorry. So, I am now going to.

Talk about the nudged forecast model. In the previous case we talked about the unknown true forecast model. M may not be equal to \bar{M} ; that means, that there is a model error. So, what is that I mean? I am going to talk about I would like to be able to simultaneously arrange G such, that it not only corrects for the model error also it corrects for the initial condition error. So, I am trying to kill 2 birds in one stroke. So, let x_1 be equal to M of x naught. x naught be the initial condition for any k greater than that M of x_k plus G times z_k minus h_k . That is the nudged model. The nudged model can be written like this. Because I am considering a linear model to be able to do things a little more precisely. For nominee I would like to be able to expose the difficulty for the linear model, if the linear model is difficult the non-linear model at least is one nudge more difficult than the linear model.

That is the aim in here in this discussion. So, my nudged model becomes 19, where the matrix a is equal to M minus $G h$. G is the gain to be determined, h is the forward operator, M is the 1 1 step transition matrix for the linear model. So, I am assuming the model is linear, the observations are also linear function of the state. So, iterating this equation 19, I get this. And z_k contains the unknown truth plus noise. So, the noise is the

embedded within the z_k term. The noise is embedded within the z_k term. I hope that is clear. So, 20 is obtained by iterating 19, a simple iteration gives you the expression. So, what is this expression the nudged state at time k depends on the state at time x_1 plus anything beyond substituting 17 in 20. So, let us go back to this is 20. What is 17? 17 is an expression for the observation based on the models solution.

(Refer Slide Time: 42:25)

FORECAST ERROR

- Substituting (17) in (20):

$$x_k = A^{k-1}x_1 + \sum_{j=0}^{k-2} A^j G [H \bar{M}^{k-1-j} \bar{x}_0 + V_{k-1-j}] \rightarrow (21)$$
- Error: $e_k = z_k - Hx_k$

$$= \underbrace{H \bar{M}^{k-1} \bar{x}_0}_{I} + \underbrace{V_k}_{II} - \underbrace{H A^{k-1} x_1}_{III} - H \sum_{j=0}^{k-2} A^j G [H \bar{M}^{k-1-j} \bar{x}_0 + V_{k-1-j}] \rightarrow (22)$$

$\underbrace{-V_k, V_{k-1}, V_{k-2}, \dots, V_1}_{\text{noise terms}}$
 $\quad \quad \quad z_k = h \bar{x}_k + v_k$

You get an expression for x_k which is the model state the forecast stage given by this expression, is a funny looking expression. A little complex expression, but I do not think there should be any difficulty in trying to verify that. Why am I trying to find that? Because I would like to be able to pin down the forecast error. So, z_k minus h of x_k is the forecast error. Now, therefore, I know z_k please remember z_k is equal to h of x_k bar. Plus, V_k h of x_k bar we have already computed in equation on 16. Based on h of x_k bar I also have in relation for z_k from 17. So, I can substitute for z_k from those equations in here. I have already computed x_k in the previous slide let us look at it once more that is the equation 20. So, substituting all these things, what do I get? I get an explicit expression for the forecast error in the nudging model. Why is that? If I want to be able to compute the forecast error covariance, the serial correlation I need to be able to get an explicit expression for the forecast error itself that is the first step. And that is what we have accomplished. So, look at the structure of 22.

22 has several terms. This is the first term. This is the second term, this is the third term, this is the 4th term is the summation. The 4th term itself is a sum of 2 terms, but among all these V_k is a noise term V_{k-1} is a noise term. So, there are 2 nice terms, the rest of it are deterministic terms. So, the error is noisy. You can also see the error of time k depends on V_k . As well as error I am the; I am sorry, the noise at time V_k as well as the noise at time 0 to yeah, 0 to timetables $k-2$. So that means, there is a serial dependency among all these noise expressions. So, when J is you can you can really see. So, I am I am I am depending on V_k .

Then when J is 0, that depends on V_{k-1} . So, let me write that down. Then J is equal to 2 that depends on the V_{k-2} . When J is equal to $k-2$, that depends on V_1 . So, therefore, e_k the error d_k does not only depend on V_k , but also the entire sequence. In the past it is this dependency of e_k , on the entire not noise sequence up to including time k , that it uses the serial correlation. I hope that part is clear to you. It is this serial correlation I am now going to have to extract.

(Refer Slide Time: 45:43)

DECOMPOSITION OF FORECAST ERROR

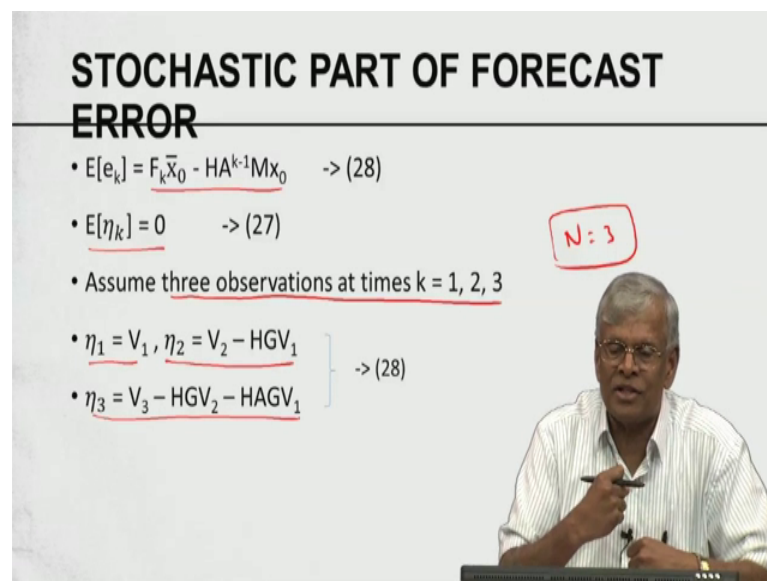

- $e_k = [F_k \bar{x}_0 - H A^{k-1} M x_0] + \eta_k \rightarrow (23)$
- $F_k = [H \bar{M}^k - H \sum_{j=0}^{k-2} A^j G H \bar{M}^{k-1-j}] \bar{x}_0 \rightarrow (24)$
- $\eta_k = V_k - H \sum_{j=0}^{k-2} A^j G V_{k-1-j} \rightarrow (25)$
- First term on the r.h.s of (23) is deterministic and η_k is the stochastic part

$A: M - G H$

I am now going to rewrite this expression e_k for the sake of convenience, your deterministic part plus the random part. The deterministic part has this expression the random part has this expression. So, 24 and 25 correspond to the domestic part of the forecast error, and the random part of the forecast error. So, you can see 23 is deterministic η_k is stochastic. What is the stochastic part? Stochastic part is again the

noise. From the past the noise from the present, the past noise are weighted by the powers of A and you may remember A is equal to M minus G H. So, so what does it mean? The random part of the forecast error depends on the model dynamics depends on the forward operator it depends on the model dynamics A it depends the forward operator H, it depends on to be chosen the matrix G which is the gain matrix to be used in nudging. And of course, all of the errors in the observation starting from time 0 to this time to the time k.

(Refer Slide Time: 47:06)

STOCHASTIC PART OF FORECAST ERROR

- $E[e_k] = F_k \bar{x}_0 - H A^{k-1} M x_0 \rightarrow (28)$
- $E[\eta_k] = 0 \rightarrow (27)$
- Assume three observations at times k = 1, 2, 3
- $\eta_1 = V_1, \eta_2 = V_2 - H G V_1$
- $\eta_3 = V_3 - H G V_2 - H A G V_1$

$\rightarrow (28)$

N: 3

Therefore, the expected value of e_k is equal to the deterministic part. The expected value of η_k the random part is 0. Now I am going to further. If I assume the a general value of n, the expressions are more gets more complex. So, instead of n, I am thus assume n is equal to 3 to just to get a feel for the expressions in this in this in this quick discussion. So, let us assume I have 3 observations at time k is equal to 1, 2 and 3. And so, by specializing this. Now look at this now the previous expressions, they go for k 1 to n. N is the last observation time. To simplify to get of to get that aha feeling I am simply going to assume n is equal to 3 with our loss of generality.

So, if I substitute n is equal to 3 and simplify, the expression there the expression for the random part of the forecast error which is eta. Eta that is look at this, now eta one depends on V 1 eta 2 depends on V 1 and V 2 eta 3. Depends on V 1 V 2 V 3 eta 4 will depend on V 1 V 2 V 3 V 4. So, that this means etas are correlated. It is this correlation

makes the 4DVAR scheme, little defective in the sense they have not taken, the entire weight function that accounts for the serial correlation.

(Refer Slide Time: 48:46)

TEMPORAL FORECAST ERROR COVARIANCE – N = 3

- $C_{ij} = E[\eta_i \eta_j^T]$ for $1 \leq i, j \leq N$
- $C_{11} = E[\eta_1 \eta_1^T] = R$
- $C_{22} = E[\eta_2 \eta_2^T] = R + HGRG^T H^T$
- $C_{33} = E[\eta_3 \eta_3^T] = R + HGRG^T H^T + HAGRG^T A^T H^T$
- $C_{21} = E[\eta_2 \eta_1^T] = -HGR$
- $C_{12} = E[\eta_1 \eta_2^T] = -RG^T H^T$

$V_k \sim N(0, R_k)$
 $R_k \equiv R$

$C = \begin{bmatrix} c_{11} & c_{12} & c_{13} \\ c_{21} & c_{22} & c_{23} \\ c_{31} & c_{32} & c_{33} \end{bmatrix}$

A simple exercise in statistics, computation of correlation tells you C_{ij} which is the correlation between errors at time i and errors at time j is given by expected value of $\eta_i \eta_j^T$. In the case when n is equal to 3, $\eta_1 \eta_1^T$ is given by R . What is R ? R so, I am please go back now. V_k is equal to M of R_k , I am it is not is generally assumed R_k is identically equal to R , why v_k s are coming from instruments. When we buy instruments, we buy instruments in bulk. So, I am going to assume all the instruments, that make measurements are the same type; that means, the covariance of the error the error characters of the instruments are the same. So, R_k does not depend on k R_k simply is R . So, that is a very useful assumption. Even though the theory I can continue with R_k , I do not want to unnecessarily complicate the expressions by trying to be general. There is no loss of generality in assuming R_k is R .

So, that is R C_{22} . So, what are this? So, C is a matrix, which is C_{11} , C_{12} , C_{13} , C_{22} , C_{23} , C_{33} everything because it is symmetric, I do not have to worry about the bottom part. But I can continue the C_{21} C_{31} C_{32} . So, I am going to compute all of these elements. You can see I have computed all of these elements. Like this, look at this now R , R plus this R plus 2 terms. C_{21} C_{12} , now look at this C_{21} C_{12} , they are that transposes of each other we will talk about the symmetry of the resulting matrix in a

minute. But I am trying to give you the exact expressions for the C s. So, let me go back and remind you once more. I would like to x, I would like to be able to understand the presence of serial correlation, n observations to make life simple I assumed n is equal to 3. So, I substituted an n is equal to 3 in the expression for the forecast covariance. Especially the random part of the forecast covariance using the random part of the covariance, I am simply computing expressions for these co-variances.

(Refer Slide Time: 51:21)

TEMPORAL COVARIANCE

- $C_{13} = E[\eta_1 \eta_3^T] = -RG^T A^T H^T$
- $C_{31} = E[\eta_3 \eta_1^T] = -HAGR$
- $C_{23} = E[\eta_2 \eta_3^T] = -RG^T H^T + HGRG^T A^T H^T$
- $C_{32} = E[\eta_3 \eta_2^T] = -HGR + HAGRG^T H^T$

20

So, C_{13} C_{31} C_{23} C_{32} . You can really say can compute this. From this you can readily see they are all related. So, what if I, if they so, in the early methods based on 4DVAR what did they not use? They did not use this term. Sorry, they did not use this term, they did not use this term. So, these are the new term that comes into the picture.

And it is these new terms we are interested in in incorporating. I hope these expressions are clear. These expressions can be very explicitly evaluated by the closed form expression for the random part.

(Refer Slide Time: 52:17)

SYMMETRIC PART OF C

- The correct term $J_3(G)$ in (13) is a quadratic form with symmetric matrix C^{-1}
- Find the symmetric part: $C \leftarrow \frac{1}{2}(C + C^T)$ $C \leftarrow \frac{C + C^T}{2}$
- The inverse of this symmetric part of C is to be used in (13)
- The matrix C depends on: M, H, R

21

So, I have I have compute a matrix C. So, let us go back now. I have computed the matrix C. Please understand, quadratics in trying to consider a quadratic forms only the symmetric part of the C matters. So, the symmetric part of C. So, C is equal to C plus C transpose by 2. So, we compute C as I have done. And compute the kind of concern the symmetric part of C. So, this the new C is called the symmetric part of C. Now the correction term J 3 now look at this now the correction term J 3 in 13 let us go back. So, 13 a; this is the new J function. Z inverse is to be used here please understand, C inverse is used to be here. It is generally the k is that I need to know the weight matrix if I am going to consider the weighted least squares, I need to know the weight matrix weight matrix is C inverse I have computed C. So, in principle I can compute C inverse. Therefore, the correct term the correct term J 3. So, J 3 the correct term in 13 is the correct form with the symmetric matrix C inverse, where C is the symmetric part of the computer. So, what is this C? This is the computed C.

This is the C that is used in the left-hand side C is the one that is used in 13. So, you compute the deterministic part of the computed C, and that becomes the new C, who C inverse is the one that is going to be used in the quadratic function. The inverse of the symmetric matrix of C is the one that is used in in in in 13th. And I would like to reemphasize the fact which I have already mentioned this matrix C depends on M H and R. What is M model? What is H observation operator? What is R noise property? So, you

can readily see it the serial covariance is a function of the model the forward operator, and the noise all the 3 players in the game.

(Refer Slide Time: 54:47)

A SECOND APPROACH – KALMAN LIKE SCHEME

- Due to Vidard et. al (2003)
- Uses Kalman filter like predictive part and combines it with the conventional nudging scheme
- First step: $x_k^f = M(x(k-1)) \rightarrow (29)$
- Second step: $x_{k+1} = x_k^f + G[Z_k - h(x_k^f)] \rightarrow (30)$

nudging

The slide features a presenter in the bottom right corner, a man with glasses wearing a light-colored striped shirt, gesturing with his right hand. The text on the slide is black, with the title in bold. The equations are underlined, and the word 'nudging' is written in red cursive below the second equation.

So, I have now completed one aspect of the estimation problem for the optimal G. This is using 4DVAR. So, we talked about what they did, and we talked about what is wrong with it, and we also talked about what is the meaningful way to correct it. Now I am quickly going to provide a review of the second approach that was used in the post 90 era based on 2 stage Kalman. Like scheme it was introduced by a group of French atmospheric scientist vidard et al 2003. This uses a Kalman filter like predictive part that combines it with a conventional nudging scheme. So, you can readily see so, you can now see the following idea. If you knew some of the basic approaches to assimilation that we have covered in this class you can hybridize these methods to be able to generate newer methods.

So, in this course, we are not going to be talking about all possible methods of hybridization. We are going to be we have described all the methods in their purest form. Because before you can hybridize you need to understand what is the power of each of these techniques. Therefore, this being the first level course at the graduate level we have emphasized. All the basic tools which if well understood, not only be applied directly also can be used to devise newer schemes for data simulation and other problems; that is the idea. So, this is an example of such hybridization. So, what is the thing in here. The

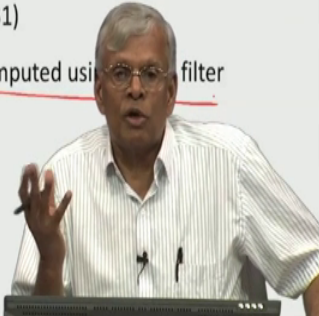

first 2 step is the following. Let x_{k-1} be the state I know I am using the model to create a forecast. The second step is I am going to do an analysis, which is forecast plus G times z_k minus h of f . So, what is this? This is the nudging part. So, you make a forecast. And then you create an analysis. The forecast comes from the model.

The analysis comes from the nudging the nudging uses a G . G plays a role of a Kalman filter. And they would like to be able to determine G . Using method similar to the arguments of Kalman filter. You can see the how the hybridization comes into play. So, that is what I am going to quickly describe.

(Refer Slide Time: 57:18)

OBJECTIVE FUNCTION

- Define $d_k = z_k - h(x_k^f) \in \mathbb{R}^m$
- $d(1:N) = (d_1^T, d_2^T, \dots, d_N^T)^T \in \mathbb{R}^{Nm}$
- $J_n(x_0, G) = \frac{1}{2} d^T(1:N) G^T (P^f)^{-1} G d(1:N) \rightarrow (31)$
- $P^f \in \mathbb{R}^{Nm \times Nm}$ – Model error covariance computed using filter

So, define d_k which is equal to z_k minus h of x_k^f , which is the innovation. The new information that G_k contains other than what the observation gives you. So, d is the vector of such innovations. D is again a vector of size Nm now. I am going to concoct $Nm \times Nm$ J_n x naught of G , J_n is called the nudging induced a cost function. So, that is equal to the transpose of this.

G transpose p^f inverse G d f n . So, you can think of these 3 as part of the weight matrices. P^f is the forecast error covariance. So, that is very similar to the one that comes in 4DVAR like scheme. Here, because of the way that G appears in in in equation 30. 31 is a very natural way to be able to consider a J function. So, the model error covariance. So, here look at this now in here p^f is the model error covariance. Using Kalman filter, you may realize even if the model is linear, computing the forecast

covariance involves 2 matrix multiplication. So, computationally it is much more expensive than the 4DVAR based idea.

(Refer Slide Time: 58:57)

OBJECTIVE FUNCTION

- $J_b(x_0) = \frac{1}{2}(x_0 - x_b)^T B^{-1}(x_0 - x_b) \rightarrow (32)$
- $J_2(G) = \frac{1}{2} \sum_{k=1}^N \langle e_k, R_k^{-1} e_k \rangle \rightarrow (33)$
- Define

$$Q_3(x_0, G) = J_n(x_0, G) + J_2(G) + J_b(x_0) \rightarrow (34)$$
- Minimize Q_3 using the adjoint method when the nudged forecast is used as a strong constraint

Therefore, they concocted several components for the overall minimization. One is the background term. What is background term? X naught until now we did not worry too much about x naught. So, initially I may allow the error, but as the system picks up in time the error will reduce that was the basic idea. Now they would like to be able to start with some background information for the model initial state itself. So, that goes to show you the flexibility of how many such terms if you knew you can add to the objective function to be able to create um a solution that takes care of several pieces of information that you may want to bring to barrel the problem. So, J 2 is essentially the sum of square of a criterion. Please remember, they used R k, yes. We have now argued use of R k is not correct because the forecast errors are correlated.

So, in that sense the use of R k in 331 essentially closer that I to the presence of serial correlation. So, what is the best way to do it? You still need to be able to get an expression for the forecast error, and need to be able to compute the serial correlation. Essentially, you are trying to talk stochastic dynamic models with stochastic observation within the context of nudging. So, when you are trying to do everything stochastic you need to call spade a spade and using R k does not fit that pattern. i that is one of the observations that we have made. So, you can cut a new cost function. Please understand,

until now we only consider the cost function is a function of G . Now the cost function is a function of x naught and G .

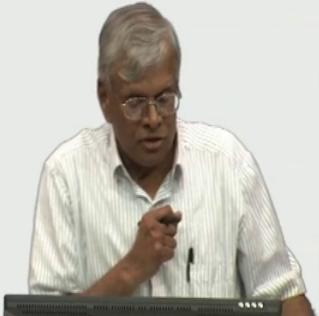

So, it is a slightly extended formulation. So, J and G we have already seen $J^2 G$ we have already seen $J^b x$ naught. So, there is a penalty coming out of x naught, there is a penalty coming out of G there is a penalty coming out of x naught and G . So, our objective is to minimize not d^3 . I am sorry, it is Q^3 , sorry minimize Q^3 , using the adjoint method. When the nudging model is used as a strong constraint now look at this. Now again they concoct a common like scheme, but they want to be able to find the initial condition, and optimal G by method similar to the adjoint method when using the adjoint the nudged model as a strong constraint. You can see the power of the 4DVAR like principles where you can apply it repeatedly whether it is initially whether it is estimating the initial state or parameters or anything else.

So, in this case G is a parameter, you can think of it for the nudge model.

(Refer Slide Time: 62:05)

A CORRECT FORMULATION

- Since the forecast errors are correlated, we need a correct $J_2(G)$ term by using the temporal Covariance matrix as shown above

Since the forecast errors are correlated, we need to correct $J^2 G$. Please understand, we need to be able to correct $J^2 G$ $J^2 G$ is given by 33. So, this is what we talked about. R_k the use of R_k inverse. So, all the other terms are closer. The only term that does not fit the bill is; because, 33 relates to the total sum of squared errors weighted sum of squared errors the waiting is not appropriate, the waiting is incorrect. So, we can again correct the weight function by appropriately computing the serial correlation. So, the

temporal covariance estimation is an important part of this. We only cited the need for computing this temporal correlation.

We have not done this explicitly. I think it will be an interesting exercise for somebody to be able to take up this 2-stage nudging scheme, that involves 4DVAR and the Kalman like scheme. And compute the serial correlated errors. And if you if you use that you should be able to find out what is a good scheme, what is the good method. So, that could in my view a good starting point for probably a master's thesis.

(Refer Slide Time: 63:29)

EXERCISES

- 1) Assume $M = \bar{M}$, that is, forecast model is perfect and $H = I$. Simplify the expression for F_k and verify $F_k = A^k = (M - G)^k$
- 2) Let the true model be given by $\bar{x}_{k+1} = m\bar{x}_k$ with \bar{x}_0 as the initial condition and $Z_k = \bar{x}_k + V_k$ with $V_k \sim N(0, \sigma^2)$ be the observations. Let the nudged forecast dynamics be given by

$$\begin{aligned}x_{k+1} &= mx_k + g(Z_k - x_k) \\ &= ax_k + gZ_k \text{ with } a = m - g\end{aligned}$$

- a) Following the developments, compute the temporal correlation matrix C the forecast error using $n = 4$ observations at $k = 1, 2, 3$ and 4
- b) Plot $J_3(G)$ vs g using one set of realizations of Z_k , $1 \leq k \leq 4$
- c) Generate another set of 4 observations and plot $J_3(g)$ vs g
- d) Compare and comment on $J_3(g)$ in (b) and (c)

26

With this we have provided you a major all the major ideas that relates to the development of nudging schemes. We have given several exercises there are extensions of the discussions that we have had.

S.Lakshmivarahan and J. Lewis (2013) "Nudging Methods: A Critical Overview", Chapter 2 in S. K. Park and L. Xu (Eds) "Data Assimilation for Atmospheric, Ocean and Hydrologic Applications", Vol II Springer Verlag

27

This module follows a paper that we wrote in 2013. Lakshmivarahan and Lewis, nudging method a critical overview. This appeared as a chapter 2 in a book entitled data assimilation for atmospheric ocean and hydrological application. It is the second volume published by springer Verlag in a series, edited by Sangee Park and l x. And that paper contains lot more information about basic nudging. We also leaded to the relation between observer theory as was developed by Leuenberger in 19, the early 1960 62 63 64 in the time frame work. And in that in our paper in our critical review, we have talked about the intrinsic relation between observer theory and the nudging theory to be able to see how observer theory can help to be able to design better nudging schemes. Nudging schemes are general schemes, which are which are very useful class of methods for forcing a model towards the observation by using the notion of this state feedback. So, with that we conclude our discussion, an introductory discussion of nudging methods.

Thank you.
