Outline

In this lecture we will discuss

1. Successive Integration of Two First-Order Equations

So we have seen how one can solve second Order Differential Equations which are linear and which have constant coefficients. We solved the homogeneous version, and then we looked at the inhomogeneous equation. So, in this lecture, we will look at a clever way of solving the same class of equations, but suppose we have forgotten about these methods right.

So, there is a way to just solve a second order differential equation simply from the knowledge of the first order differential equation. So, it's a, it ends up being two first order differential equations right provided you are working with linear differential equations, you know there is this prescription available. So, let us look at this clever approach in this lecture ok.

(Refer Slide Time: 01:07)

Successive Integration of Two First-Order Equations

Consider the general equation

$$(D - a)(D - b)y = f(x).$$

We can define

$$u = (D - b)y$$

Therefore the differential equation is

$$(D - a)u = f(x),$$

which is the same as

So, we are given you know this general equation D minus a times D minus b times y is equal to f of x right. So, you know the, you know our discussion started with you know putting f of x to be 0. We look at the homogeneous version from where we write down the solution for the homogeneous differential equation, and then we have to find a particular solution right.

We will look at how you know there are methods to solve to find the particular solution and so on right. Then we of course, if we can do this, then we have the solution. So, here we look at you know this differential equation D minus a times D minus b acting on y is equal to f of x as a two-step process. So, suppose u is equal to D minus b acting on y .

So, this is a first order operation acting on y is equal to u . And then so you see that D minus a times u is equal to f of x is a first order differential equation right. So, u is known, and f of x is known, a is just a constant. So, in fact, we should be able to solve for this u right.

(Refer Slide Time: 02:16)

Consider the general equation

$$(D - a)(D - b)y = f(x).$$

We can define

$$u = (D - b)y$$

Therefore the differential equation is

$$(D - a)u = f(x),$$

which is the same as

$$\frac{du}{dx} - au = f(x).$$

But this is a first-order linear differential equation that we already know how to solve. Solving we would get a constant. If we plug this solution for $u(x)$ into

02:16

So, because this is nothing but $D u$ by $D x$ minus $a u$ is equal to f of x . So, this is a first order differential equation. We have the prescription. We know how to find the integrating factor, multiply throughout by the integrating factor, then you have an exact differential equation. So, you write the left hand side as a total derivative. And then you just integrate, and then at least you have a formal solution for this right.

So, suppose you manage to find this formal solution right. Well, I mean it will depend on this function f of x how reasonable a function it is and so on the details you know one has to there may be struggle involved, but at least there is a principle you know a prescription available for this problem, and so that is what we are describing.

So, suppose you managed to find the solution u of x because it is a first order differential equation, and then we plug this back into our definition of u . So, but what is u ? u is D minus b acting on y . y is unknown. So, we have $D y$ by $D x$ minus $b y$ is equal to u of x . So, in fact, we can think of this u of x itself as like a forcing function for another first order differential equation right.

So, if we can solve this first order differential equation as well, so not only you know do would we like f of x to be a reasonable function, but it should yield for us another reasonable function u of x such that this equation also you know if we can integrate it out, and finally, we will have a solution y which will have two you know free constants right.

Because the first order equation will give us one free constant, and then when we integrate a second time that is going to give us another free constant. So, there will be two free constants which are characteristic of a second order linear differential equation right.

(Refer Slide Time: 04:06)

Example

Let us solve the differential equation

$$\frac{d^2y}{dx^2} + \frac{dy}{dx} - 2y = e^x$$

by the direct method described above. We start by writing the above differential equation as:

$$(D+2)(D-1)y = e^x$$

Defining

$$u = (D-1)y$$

the differential equation we must solve is:

$$(D+2)u = e^x$$

or

$$\frac{du}{dx} + 2u = e^x$$

which is a linear first-order differential equation, that we know and love. Multiplying by the integrating factor e^{2x}

So, let us look at an example to illustrate how this works out. So, suppose we want to solve this differential equation $d^2y/dx^2 + dy/dx - 2y = e^x$. We know how to solve this equation by the other method we have already described. We would find the homogeneous equation and find its two roots. Write down the complementary function, then look for a particular solution for this right.

So, first we will based on the complementary function, we can you know make the right ansatz for the particular solution, find the, you know coefficient method of undetermined coefficients we plugged it in plug it in. And extract the coefficients, we find a particular solution, and then we just simply add it to the complementary function. But here let us do it by the direct method that we just described.

So, we have $D + 2$ times $D - 1$ times y is equal to e^x . So, here well we could have you know factorized in either way could have thought of it as $D - 1$ times $D + 2$ times y equal e^x which is which I will leave it to you as homework to work it out in the other direction. So, by the way I mean you see that the roots here are minus 2 and 1.

So, probably you would run into difficulties if you try an ansatz of the form e to the x , you will have to try x times e to the x right. So, this is if you are doing it by the other way which is to find a particular solution. But anyway all of that is bypassed here in this approach. So, we have D plus 2 times D minus 1 times y is equal to e to the x .

So, we define u is equal to D minus 1 times y . And so we must solve the differential equation D plus 2 acting on u is equal to e to the x , so that is du by dx plus 2 times u is equal to e to the x .

So, we have to multiply throughout by this integrating factor which is e to the integral it is just $2x$ in this case integral of $2 dx$ will be $2x$. So, you have to multiply throughout with e to the $2x$. And we have e to the $2x$ times du by dx you know there would be some constant which does not matter.

(Refer Slide Time: 06:24)

which is a linear first-order differential equation, that we know and love. Multiplying by the integrating factor e^{2x} , we have:

$$e^{2x} \frac{du}{dx} + 2u e^{2x} = e^{3x}$$

which is the same as:

$$\frac{d(e^{2x}u)}{dx} = e^{3x}$$

therefore

$$e^{2x}u = \frac{e^{3x}}{3} + c_1$$

thus

$$u = (D-1)y = \frac{e^x}{3} + c_1 e^{-2x}$$

Now we have one more linear first-order differential equation to solve:

$$\frac{dy}{dx} - y = \frac{e^x}{3} + c_1 e^{-2x}$$

Multiplying throughout by the integrating factor e^{-x} , we have:

So, we have e to the $2x$ times du by dx plus $2u$ e to the $2x$ is equal to e to the $3x$ which is the same as saying the total derivative of the function e to the $2x$ times u as you can verify here is equal to e to the $3x$. Now, it is simply a matter of integrating both sides which yields for us e to the $2x$ times u is equal to e to the $3x$ by 3 plus some constant. So, we get the first free constant here.

Now, we are only halfway through. So, we have to solve the other first order differential equation which is the definition of u , u is equal to D minus 1 acting on y . So, which y is

unknown, so u is equal to D minus 1 times y . And since u is from here we have already solved for u which is e to the x divided by 3 plus c_1 times e to the minus $2x$.

So, this is the second differential equation that we must solve first order linear differential equation. So, we have dy by dx minus y is equal to e to the x by 3 plus c_1 times e to the minus $2x$. We know how to solve this. Again we have to integrate to find the integrating factor.

(Refer Slide Time: 07:35)

$\frac{dy}{dx} - y = \frac{e^x}{3} + c_1 e^{-2x}$.

Multiplying throughout by the integrating factor e^{-x} , we have:

$$e^{-x} \frac{dy}{dx} - e^{-x} y = \frac{1}{3} + c_1 e^{-3x},$$

which can be rewritten as:

$$\frac{d(e^{-x} y)}{dx} = \frac{1}{3} + c_1 e^{-3x},$$

integrating which we get:

$$e^{-x} y = \frac{x}{3} - \frac{c_1}{3} e^{-3x} + c_2.$$

Thus full general solution of the original differential equation is:

$$y = \frac{x}{3} e^x - \frac{c_1}{3} e^{-2x} + c_2 e^x.$$

We see that $y_p = \frac{x}{3} e^x$ is a particular solution, and both e^x and e^{-2x} are complementary functions, which homogeneous differential equation.

So, which in this case is just e to the minus x multiply throughout with e to the minus x . So, we have you know the right hand side simplifies you have e to the x into the e^2 minus x will become just 1 over 3 plus c_1 times e to the minus $3x$. Now, the left hand side can be written as a total derivative its d by dx of e to the minus x y is equal to one-third plus c_1 times e to the minus $3x$ integrate both sides, we get e to the minus x times y is equal to x by 3 minus c_1 by 3 times e to the minus $3x$ plus another free constant c_2 .

So, the full solution of the general equation now we are able to write down as y is equal to x over 3 times e to the x right, we divide throughout by e to the minus x . So, we get e to the x here, and minus c_1 by 3 e to the minus $2x$ plus c_2 times e to the x , so that is a full solution right. So, now looking at this full general solution, we can actually you know see how we would have perhaps got the same answer if we had used the other method right.

So, we see that y_p is equal to x over 3 times e to the x is in fact you know the particular solution it is a particular solution and then you know this minus c_1 by 3 does not matter right we could have just called this minus c_1 by 3 as some constant $c_1 e$ to the minus $2x$ and e to the x right these are the you know two solutions of your homogeneous differential equation which we could have directly got from here D plus 2 into D minus 1. So, the roots would be minus 2 and plus 1.

So, the solutions would be e to the minus $2x$ and e to the x right, so which is what we see here. So, there is x by 3 times e to the x which is a particular solution plus some constant times e to the minus $2x$ plus another free constant times e to the x right.

So, we have seen how there is this alternate method in which we could adopt brute force for a second order differential equation and then solve two consecutive first order differential equations and get to the answer. That is all for this lecture.

Thank you.
