Characterization of Constructible Numbers

(Refer Slide Time: 0:15)

We are now ready to describe what all constructible numbers look like in terms of towers of field extensions. There is just one little construction we need before we can put all this into motion. And that is following that if you can construct a then square root, you can also construct square root of a. So let us call it a Lemma maybe, if a is constructible then square root a is constructible. And how does this construction work?

(Refer Slide Time: 1:06)

And let us use GeoGebra. So to start with I have this segment OA of length 1 and I mark off the left of O another segment of length A and now I am going to construct a segment of length square root A. So firstly what I do is I find the midpoint of A and B, let us call it C. So this we can do it again using straightedge and compass I already did this when we were trying to find a, construct square root of 2.

So we find the mid-point and then we draw a circle I am only drawing half of it here with center C passing through A and therefore also B because C is this midpoint of AB. So we construct the circle C and through O we construct a perpendicular to the line that passes through O A and B and then let us call the intersection of this new line with the circle D, with a circle C to be capital D. And now you look at, you join the line segments BD and you join the line segments BA, I do not really need to do this but I am doing it explain to you something.

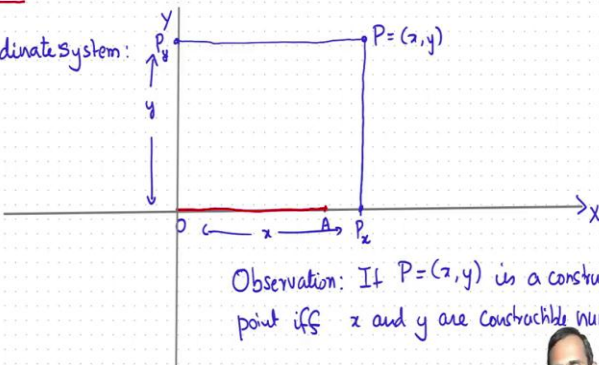

So now you look at these 2 triangles ODB and a OAD in that order. These are similar triangles because I guess this is easy this angle here at B and this angle here at A they add up to 90 degrees and so that shows this angle here at B is the same as this angle ADO is same as the angle DBO. And so these 2 triangles are similar. Now since these 2 triangles are similar if I take this length OD and divide it by a that is the same as 1 divided by length OD. And so this length OD it cannot be anything but square root of a. It so having constructed a we can also construct square root of a as this construction shows.

(Refer Slide Time: 3:22)

Characterization of Constructible numbers

Lemma: If a is constructible, then \sqrt{a} is constructible

Coordinate system:

Observation: If $P=(x,y)$ is a constructible point iff x and y are constructible numbers.

So that is the proof of this Lemma and let us move on. So the other thing we need to do is to be able to construct a coordinate system. This will be convenient because right now what we have said is that a constructible number is the distance between 2 constructed points and you may have a lot of constructed points floating around it is difficult to keep track what are all the constructible numbers that you have created so far.

So we will create coordinate system and this we can do with straightedge and compass I will just do it by hand here. So you start with your lines segment OA and then you can draw a perpendicular to it using straightedge and compass. So firstly in fact maybe a given OA you can draw a line that is you know the x axis as just the infinite line that passes through O and A . I need to move it up a bit. So this would be my x axis.

And for my y axis I will draw a line, so let us just remember where OA was this is OA and for the y axis I will draw a line perpendicular to it. Which I can also construct by straightedge and compass. And now if I have any point P s then I can draw a perpendicular from P to Y , to the y axis and I will call this a P subscript y or just little y and I can draw a perpendicular to the x axis and I will call this P subscript x .

So we can always construct given a point we can the firstly given O and A which we were given at the beginning of our construction, we can construct the coordinate system the x axis is the line that passes through y ending the y axis is the line perpendicular to it and if we can construct the

point P then by dropping perpendiculars we can construct the x coordinate and the y coordinate of the (P) (5:45).

So we can mark off a distance equal to the x coordinate of P and a distance equal to y coordinate of the P along the x and y axis respectively. So what we observe here is that maybe I will just call it in observation. If P equals x comma y is a constructible point then x and y are constructible numbers. But also if we can construct these distances x and y then we can mark them off along the x and y axis and draw perpendicular lines.

We can draw a line perpendicular to the y axis through this Y coordinate and a line perpendicular to x axis through this x coordinate and they will intersect in the point P . So also we can construct x and y we can the point P and with coordinates x comma y is constructible. So what I will do is I can change this from one-way implication to and if and only if. So point P is constructible if and only if its x and y coordinates are constructible numbers.

Now let us see what happens at each stage of a construction. So what at each stage of the construction you constructed at certain set of points and their coordinates would be a constructible numbers and now we can add a new point the new points we allow to add are either intersection of lines passing through the constructed points or intersection of circles with center at the constructed points and radius which is constructible or a circle and a line. So in each of this cases let us see what are the new constructible numbers we get as x and y coordinates of constructible points.

(Refer Slide Time: 8:11)

Theorem (*): Suppose $\frac{F}{Q}$ is a field

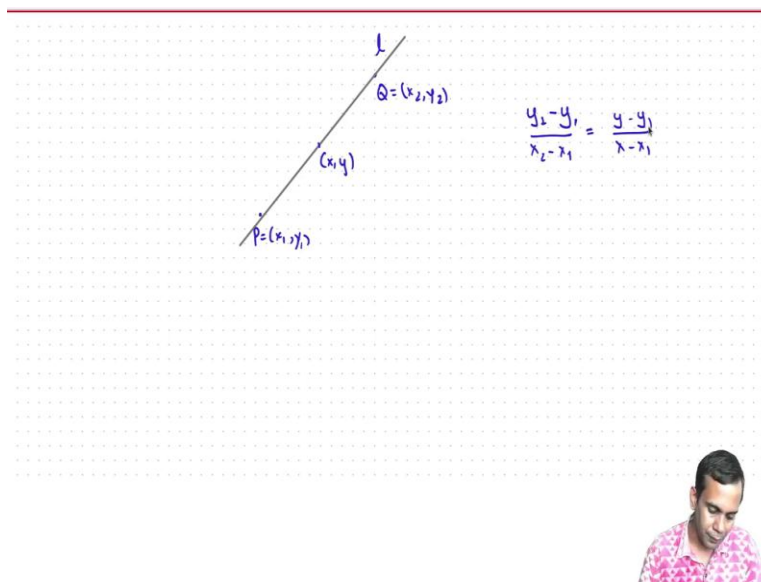

- (a) If l_1 and l_2 are lines passing through points with coordinates in F , the coordinates of $P = l_1 \cap l_2$ are in F .
- (b) If l is line passing through points with coordinates in F , C a circle with centre having coordinates in F and radius in F , then the point(s) of intersection of l and C have coordinates in a quadratic extn. of F .
- (c) If C_1 & C_2 are circles whose centres have coords in F and whose radii are in F , then their point(s) of intersection lie in a quadratic extn. of F .

So here is a theorem I will call it theorem star it going to use it later, it is going to be important in what follows. So the theorem says that suppose I have a field extension F over Q is a field. Now we look at three cases if l_1 and l_2 are lines passing through points with coordinates in F . Then the coordinates of $l_1 \cap l_2$ are in F . We do not even need to go to an extension. And b if l is a line passing through points with coordinates in F . and C is a circle with center having coordinates in F and radius having coordinates in F .

So maybe I should say center and well radius in F center having coordinates in F and radius in F , then the points of intersection of l and C they could be only one if l is tangential have coordinates in a quadratic extension of F . And the last case is where you have if C_1 and C_2 are circles whose centers have coordinates in F and radii are in F then their points of intersection again they could be just one point but they are tangential their points of intersection lie in a quadratic extension of F .

(Refer Slide Time: 12:17)

So part a is rather simple what you have to do is if you have two points P equals x_1 y_1 and Q equals x_2 y_2 then this line l that passes through them, this line l that passes through them its points will be given by an equation like you know if you have a point x comma y here then what we know is that y_2 minus y divided by, so we can assume that either x_1 is not equal to x_2 or y_1 is not equal to y_2 .

And now if I assume that x_1 is not equal to x_2 then I can write this like this y_2 minus y_1 divided by x_2 minus x_1 is equal to y minus y_1 x minus x_1 . If you want, you can move this to the other side and write it in form like this does not involve any division. And so not have to worry about x equals x_1 or x equals x_2 equals x_1 .

And then from this you can show that if you have two such lines then their point of intersection will lie in the same field that it will just you can construct it by addition and multiplication of coordinates of x_1 y_1 and x_2 y_2 . So you will have this kind of conditions for two lines, I am going to leave this as an exercise for you and move on to the slightly more interesting cases of a circle and line and 2 circles.

(Refer Slide Time: 17:38)

Proof of (c) $(u, v) \in C(x_1, y_1, r_1) \cap C(x_2, y_2, r_2)$

$$(u - x_1)^2 + (v - y_1)^2 = r_1^2 \quad (1)$$

$$(u - x_2)^2 + (v - y_2)^2 = r_2^2 \quad (2)$$

$$-2u(x_1 - x_2) - 2v(y_1 - y_2) = r_1^2 - r_2^2 \quad (1) - (2)$$

Assume $x_1 \neq x_2$,

$$u = \frac{r_1^2 - r_2^2 + 2v(y_1 - y_2)}{-(x_1 - x_2)}$$

Substitute in (1) to get a quadratic in v with coeffs. in F

$$\Rightarrow v \in F(\sqrt{D}) \Rightarrow u \in F(\sqrt{D})$$

Theorem (*): Suppose $\frac{F}{Q}$ is a field

(a) If l_1 and l_2 are lines passing through points with coordinates in F , the coordinates of $P = l_1 \cap l_2$ are in F .

(b) If l is a line passing through points with coordinates in F , C a circle with centre having coordinates in F and radius in F , then the point(s) of intersection of l and C have coordinates in a quadratic extn. of F .

(c) If C_1 & C_2 are circles whose centres have coords in F and whose radii are in F , then their point(s) of intersection lie in a quadratic extn. of F .

Now let us move on to the prove of c. We have a point that lies on two circles. So let us say u and v the circles are the first one is with radius x center x_1 y_1 and radius r_1 and also it lies in the circle with center x_2 y_2 and radius r_2 . Then what we have is that this point u and v satisfy the equations u minus x_1 squared plus v minus y_1 squared equals r_1 square. This is equation 1 and u minus x_2 squared plus v minus y_2 squared equals r_2 square, this is equation 2.

So now let us just add these equations or rather maybe subtract these equations. So we take equation 1 minus equation 2 then this quadratic terms will cancel out and we will get a linear equation involving u and v . So what we get is a minus $2u$ x_1 minus x_2 minus $2v$ y_1 minus y_2 is

equal to $r_1^2 - r_2^2$. So using this we can eliminate let say assume that x_1 is not equal to x_2 then we can write u as $r_1^2 - r_2^2 + 2v y_1 - y_2^2$ to whole divided by x_1 , negative of $x_1 - x_2$.

And so you can eliminate u from either of this equations and solve for v . So substitute in 1 to get a quadratic equation in v and with coefficients in F . And so this implies that v belongs to F square root D but then u can be recovered from v using this function here. So which also imply that u belongs to F square root D . And so u and v lie in a quadratic extension over F .

So we have shown with theorem star, we have proved theorem star which basically says that if some stage of our construction, all the points that we have constructed their x and y coordinates lie in some field F . Then any new point that we introduce at this stage of our construction its coordinates will lie in a quadratic extension of F or in F itself in case we are constructing a new point by intersecting 2 lines. But if it is a circle is involved, then it would probably lie in a quadratic extension of F .

(Refer Slide Time: 21:30)

Theorem: Any $a \in \mathbb{R}$ is constructible iff there exists a tower

$$\begin{array}{c}
 F_n \\
 | \\
 F_{n-1} \\
 | \\
 \vdots \\
 F_1 \\
 | \\
 \mathbb{Q}
 \end{array}$$

such that $[F_i : F_{i-1}] = 2$ for $i = 2, \dots, n$
 $[F_1 : \mathbb{Q}] = 2$
and $a \in F_n$.

And now with this you can kind a guess where all the constructible points come from, this is the statement a beautiful theorem now ready to prove. So a real number is constructible if and only if there exist a tower, F_n containing F_{n-1} going to F_1 containing Q such that F_i index F_i minus 1 is 2 for i equals 2 to n and also we assume that F_1 in Q degree of F_1 over Q is 2. And a number a belongs to F_n . So basically we are saying that constructible numbers are numbers that live in towers of quadratic extension.

(Refer Slide Time: 23:05)

Lemma: If every element of F is constructible, and $[E:F] = 2$ then every element of E is constructible.

Pf: $E = F(\sqrt{D})$ for some $D \in F$.

D is constructible $\Rightarrow \sqrt{D}$ constructible.

Constructible nos. form a field.

this field contains F , and \sqrt{D}
 So it contains $E = F(\sqrt{D})$ so every element of E is constructible.

So let us see how to prove this. So firstly to prove it we will have a we will first state a simple Lemma which will make the prove easier to understand that if every element of a field F is constructible and E is an extension of F with degree 2 then every element of E is constructible. So this is taking care of one step of our tower. And proof, well we have already seen that if E is a quadratic extension of F , E is of the form F square root D for some D in F .

Now if we know that D is constructible which implies that square root D is constructible. Now constructible numbers form a field and what we have seen is that this field contains F and root D . So it contains a smallest field containing both F and root D . So it contains E equals F root D . So every element of E is constructible. And that is the proof, so now we can prove a this theorem in one direction and which is that suppose a lies in a tower of quadratic extensions.

(Refer Slide Time: 25:34)

Pf of theorem Every $a \in \mathbb{Q}$ is constructible.

\Rightarrow Every $a \in F_1$ is constructible

\Rightarrow Every $a \in F_2$ is constructible

\Rightarrow

\vdots

$\Rightarrow a \in F_n$ is constructible.

F_n
| 2
 F_{n-1}
|
 \vdots
| 2
 F_1
| 2
 \mathbb{Q}

Lemma: If every element of F is constructible, and $[E:F] = 2$ then every element of E is constructible.

Pf: $E = F(\sqrt{D})$ for some $D \in F$.

D is constructible $\Rightarrow \sqrt{D}$ constructible.

Constructible nos. form a field.

this field contains F , and \sqrt{D}

so it contains $E = F(\sqrt{D})$ so every element of E is constructible.

So now suppose proof of theorem if so firstly a in \mathbb{Q} can be constructed a belong to \mathbb{Q} is constructible. Why is this? Every rational number is constructible because 1 is constructible and constructible numbers from a field. Now any so if 1 is in a field then all rational numbers are in that field. So every element of \mathbb{Q} is constructible and now applying this Lemma. So we have this you know we have this extension F_n F_n minus 1 F_1 over \mathbb{Q} .

And each of this is a degree 2, each of this extension is of degree 2. So now every element in \mathbb{Q} is constructible by this Lemma. This implies that a belongs to F_1 is constructible. So maybe I should say every a in \mathbb{Q} is constructible implies that every a in F_1 is constructible by this

Lemma. And that implies that every a in F_2 is constructible again applying that Lemma and so on, which means that every a in F_n is constructible.

So you apply this Lemma n times to show that every element of F_n is constructible. Now for the converse we will have to use theorem star. So this shows that every element of F_n is constructible. Now we want to show that if we have a constructible number then we can find a tower of quadratic extensions, so that lives in one of the fields in that tower.

(Refer Slide Time: 27:57)

For the converse: If $a \in \mathbb{R}$ is constructible, then it is the distance between two constructible points $P \notin Q$
 $\begin{matrix} P & \notin & Q \\ (x_1, y_1) & & (x_2, y_2) \end{matrix}$

$\Rightarrow x_1, y_1, x_2, y_2$ are constructible.

$$a = \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2}$$

It suffices to show that \exists tower $F_n \supset F_{n-1} \supset \dots \supset F_1 \supset \mathbb{Q}$
 such that $x_1, x_2, y_1, y_2 \in F_n$.

Suppose the construction of $P \notin Q$ involves the construction of a seq. of points $P_1 = (x_1, y_1), P_2 = (x_2, y_2), \dots, P_N = (x_N, y_N)$
 Let $F_i = \mathbb{Q}(x_1, y_1, \dots, x_i, y_i)$

Theorem (*): Suppose F is a field
 \mathbb{Q}

(a) If l_1 and l_2 are lines passing through points with coordinates in F , the coordinates of $P = l_1 \cap l_2$ are in F .

(b) If l is line passing through points with coordinates in F , C a circle with centre having coordinates in F and radius in F , then the point(s) of intersection of l and C have coordinates in a quadratic extn. of F .

(c) If $C_1 \notin C_2$ are circles whose centres have coords in F and whose radii are in F , then their point(s) of intersection lie in a quadratic extn. of F .

So for the converse, so if a in \mathbb{R} is constructible then it is the distance between two constructible points. Let us call them P and Q so let say P is $x_1 y_1$ and Q is $x_2 y_2$. So this means that the

coordinates x_1, y_1, x_2, y_2 are constructible. So it which and so now this distance between P and Q is equal to square root of $x_1^2 - x_2^2 + y_1^2 - y_2^2$. So this is in a quadratic extension contained in these points.

So this means that of course if these are constructible then a is constructible. So it suffice to show, so a is a quadratic extension containing the field containing x_1, y_1 and x_2, y_2 . So it suffice to show that there exist a tower now to just save space I will write my tower horizontally F_n contains F_{n-1} contains F_1 contain in Q and each of these of degree 2 of quadratic extensions, such that x_1, x_2, y_1 and y_2 are F_n .

So now let us, so these point P and Q are constructible. So let us say that the construction of the points P and Q takes place through several steps. So suppose the construction of P and Q involves the construction of a sequence of a points, let say P_1, P_2, P_n in this order such that each P_i is constructed by joining either two lines in the previous step of the construction or a circle and a line in the previous step of the construction or two circles in previous step of the construction.

Then what we have is that let F_i be the field extension of Q containing let us say that maybe I will just say P_1 is x_1, y_1 , P_2 is x_2, y_2 , P_n x_n, y_n . Then if you look at this F which is x_1, y_1 up to x_i, y_i for i goes from 1 to n . Then by theorem star which we have here, so each of these points is constructed by intersecting two lines at the previous step or intersecting a circle and a line at the previous step or intersecting 2 circles at the previous step.

(Refer Slide Time: 33:01)

$[F_i : F_{i-1}] \leq 2$ for each i .
 \therefore the coordinates of P and Q lie in a tower of quadratic extensions.

Corollary: If $a \in \mathbb{R}$ is constructible, $[\mathbb{Q}(a) : \mathbb{Q}] = 2^r$ for some r .
 In particular a is alg.

Pf: $[F_n : \mathbb{Q}] = 2^n$

F_n
F_{n-1}
F_{n-2}
\vdots
F_1
\mathbb{Q}

F_n
$\mathbb{Q}(a)$
\mathbb{Q}

$[F_n : \mathbb{Q}(a)] [\mathbb{Q}(a) : \mathbb{Q}] = 2^n$

So theorem start will tell us that, theorem star will now tell us that F_i index F_i minus 1 is either 1 or 2. And therefore we have that coordinates of P and Q lie in a tower of quadratic extensions as claimed. A very interesting corollary of this is the following. If a number a is constructible then you look at the degree of the extension $\mathbb{Q}(a)$ over \mathbb{Q} , this has to be a power of 2. Some non-negative integer r , in particular a algebraic of course.

This is because we have a tower $F_n F_{n-1} \dots F_1 \mathbb{Q}$ and each of these extension is of degree 2 the degree of F_n over \mathbb{Q} is going to be 2^n , it is going to be the product of these extensions. And now what we have is, if our element is constructible then it lies inside in some F_n like that. So $\mathbb{Q}(a)$ is an extension that is between \mathbb{Q} and F_n and so $F_n \mathbb{Q}(a)$, $\mathbb{Q}(a) \mathbb{Q}$ this is 2^n . So the only possibility for $\mathbb{Q}(a)$ the index the degree of $\mathbb{Q}(a)$ over \mathbb{Q} is that it has to be the 2^r for some r less than or equal to n .
