Lecture – 16
Stability of Linear Autonomous Systems - II

Hello friends, welcome to this lecture, in this lecture, we will continue our study of stability of non-linear system, if you recall in previous class, we have define; what do we mean by stability of a solution of a nonlinear system.

(Refer Slide Time: 00:46)

$$\begin{aligned}
 & \dot{x} = f(t, x) \\
 & \checkmark \quad x = \phi(t), \quad \psi(t) \\
 & \checkmark \quad \|\phi(t_0) - \psi(t_0)\| < \delta \\
 & \Rightarrow \|\phi(t) - \psi(t)\| < \epsilon \\
 & \forall \epsilon > 0 \quad \exists \delta > 0 \quad \checkmark \quad f(t, x) = Ax \\
 & \dot{x} = f(t, x) \Rightarrow \boxed{\dot{x} = Ax}
 \end{aligned}$$

For example, if you have a say $\dot{x} = f(x)$ and we have a solution like $x = \phi(t)$, then we say that this $\phi(t)$ is a stable solution provided that if you take any other solution $\psi(t)$ of $\dot{x} = f(x)$ such that initially, let us say the initial point is t_0 , t_0 is a initial point where this differential equation is start functioning or t_0 is some initial point such that this $\phi(t_0) - \psi(t_0)$ is $<$ some very small quantity call it delta.

And so, if we take a any other solution $\psi(t)$, such that this norm, this is basically norm; norm of $\phi(t_0) - \psi(t_0)$ is $<$ delta implies that that norm of $\phi(t) - \psi(t)$ is $<$ some epsilon, so it means that for, I can call this as for every epsilon $>$ 0, they exists a delta $>$ 0 of course, it is depending on epsilon such that this quantity is true means norm of $\phi(t) - \psi(t)$ is $<$ epsilon, whenever the they are near to say, whenever norm of $\phi(t_0) - \psi(t_0)$ is $<$ delta.

So, if for every $\psi(t)$, we have this condition true, then we say that $x = \psi(t)$ is a stable solution of $\dot{x} = f(x)$, so this is how we have defined the definition, defined the stability of a given solution now, let us focus on a particular case of this, when let us assume that $f(x)$ is simplify and we can write it like A of x , so it is an autonomous system, so now $\dot{x} =$ in place of $f(x)$, we are considering a particular special case of this that is $\dot{x} = Ax$.

It means that we are considering that $f(x)$ is given by A of x and then we try to get some condition on say, coefficient matrix A such that the every solution of x is stable or unstable or say half stable, something like that, so let us try to find out the condition on the coefficient matrix A such that we can talk about the solution of this linear system $\dot{x} = A$ of x .

(Refer Slide Time: 03:32)

Let A be a real matrix of size $n \times n$ matrix. The stability of any solution of the linear autonomous differential system

$$\dot{x} = Ax \quad (1)$$

may be determined completely as we have methods available to find all the solutions of a given linear system. In this regard following two remarks are extremely useful:

$$\|\psi_j(t)\| < \epsilon \quad \forall j=1, \dots, n$$

Remark 1

- 1 Any solution of a given linear system (1) is stable(unstable) if the equilibrium solution $x(t) \equiv 0$ of the linear system is stable(unstable) ✓
- 2 To show that the n quantities $\|\psi_j(t)\|$, $j = 1, \dots, n$ are small can be reduce to check that only one quantity is small if we choose our norm as supremum norm $\|\psi(t)\| = \max\{|\psi_1(t)|, \dots, |\psi_n(t)|\}$. ✓

Considering the above two remarks we may check the stability of any solution of the given linear system (1) with the help of the following theorem:

So, now let us move to this, so let A be a real matrix of size n cross n matrix, the stability of any solution of the linear autonomous differential equation $\dot{x} = A$ of x and this may be defined by this may be determined completely as we have methods available to find out all the solution and we have already discussed the method to find out the complete solution of $\dot{x} = Ax$ and once we have complete solution of $\dot{x} = Ax$, we can find out the behaviour of its solutions.

So, it means that we have methods available to find out all the solution of a given linear system and in this we can discuss the stability of any solution of $\dot{x} = Ax$ in complete manner, so in

this regard we have following 2 remarks and first remark is that any solution of a given linear system $\dot{x} = Ax$ is stable or unstable if the equilibrium solution $x(t) \equiv 0$ of the linear system is stable.

So, it means that what this remark wants is that if $x(t) \equiv 0$ is a stable then, any solution is a stable and vice versa means, if any solution of a given linear system is a stable, then zero solution is also stable, so it means that here the stability behaviour is equivalent whether it is any solution or a zero solution, so it means that zero solutions will give you the stability behaviour of any solution.

So, if zero solution of linear system is a stable, then any solution of linear system is a stable and if zero solution of linear system is unstable, then any solution of the linear system is also unstable, so this is the first and very, very important remark. Now, second remark is that since here we have to calculate n quantities, because we are talking about that this $\phi(t) - \psi(t)$ is mere, so it means that we have an and we are assuming that $\phi(t)$ and $\psi(t)$ are column vector function of size $n \times 1$.

So, it means that we have to check that n quantities like $\psi_j(t) \quad i = 1 \text{ to } n$ are small if we are taking, considering the stability of zero solution, then we have to check that norm of $\psi(t)$ is $< \epsilon$ and this implies and; this implies that every component likes $\psi_j(t)$ is $< \epsilon$ for every $j = 1 \text{ to } n$. So, rather than checking for n quantities, $\psi_j(t)$, we have to; we will use not we have to; we are using one different form of norm.

Here, we are taking this norm which is known as maximum norm, so here we simply take norm of $\psi(t) = \text{maximum of modulus of } \psi_1(t) \text{ up to modulus of } \psi_n(t)$, so here we are using the supremum of say, maximum of each $\psi_i(t)$ and then we call this as norm of $\psi(t)$, so if we are using this, then we can stabilise our result only in terms of this norm and if it is true for this norm, then it means that each $\psi_i(t)$ is $< \epsilon$.

(Refer Slide Time: 07:17)

$x' = Ax$ ✓
 $x(t) \equiv 0$ is stable soln
 \Rightarrow Any soln of $x' = Ax$ is also stable
 \Rightarrow Any two soln of $x' = Ax$ are any two soln of $x' = Ax$
 \Rightarrow $Q(t), \psi(t)$ are any two soln of $x' = Ax$
 \Rightarrow $Q(t) - \psi(t)$ is also a soln of $x' = Ax$
 \Rightarrow Whenever $\|0 - z(t_0)\| < \delta$
 \Rightarrow $z(t)$ is any soln of $x' = Ax$
 \Rightarrow Whenever $\|Q(t_0) - \psi(t_0)\| < \delta$
 \Rightarrow $x = Q(t)$ is a stable soln.

And hence we can have the required result, so first let us check the first one the let us verify this remark 1 and it says that you look at here, we simply say that we have a system $x' = Ax$ and we say that if $x(t) \equiv 0$ is stable solution, this implies that any solution of $x' = Ax$ of x is also stable, so let us take in particular let us say any solution let us take, $\psi(t)$ as one of the solution and we want to say that if $x(t) \equiv 0$ is stable.

Then we want to check that $\psi(t)$ which is the solution of $x' = Ax$ of x is also stable, now we already know that in case of homogeneous linear system, we already know that if $\psi(t)$ and $\psi_1(t)$ are any two solutions of $x' = Ax$ of x , then $\psi(t) - \psi_1(t)$ is also a solution of $x' = Ax$ that is what we already know that even this solution set forms a vector space, right, so for $x' = Ax$ of x .

So, it means that if $\psi(t)$ and $\psi_1(t)$ are any two solution then their difference is also a solution of $x' = Ax$ of x . Now, let us say that zero solution is a stable means, we simply say that if you take any other solution, let us call it $z(t)$, so $\|0 - z(t)\| < \epsilon$, whenever it is for every $\epsilon > 0$, they exist a $\delta > 0$, such that this $\|0 - z(t_0)\| < \delta$, whenever $\|0 - z(t_0)\| < \delta$, where $z(t)$ is any solution of $x' = Ax$ of x .

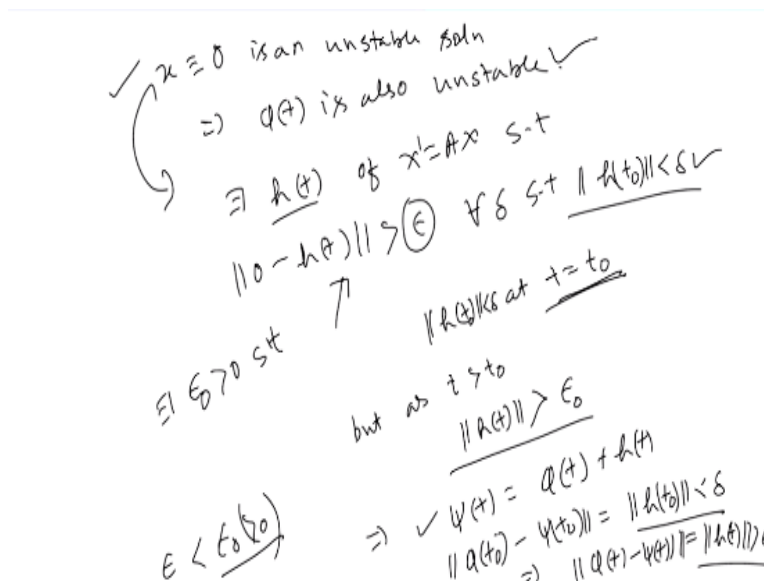

Now, since $z(t)$ is any solution and we already know that if $\psi(t)$ is a fixed solution of $x' = Ax$ for which we want to find out the stability criteria and let us say that $\psi_1(t)$ is any solution so, fix

$\phi(t)$ and $\psi(t)$ is any solution, so it means that $\psi(t)$ is an arbitrary solution of $\dot{x} = A$ of x and $\phi(t)$ is a fixed solution $\dot{x} = A$ of x , then we can say that $\phi(t) - \psi(t)$ is also an arbitrary solution of $\dot{x} = A$ of x .

So, in particular, I can take the expression $z(t)$ as $\phi(t) - \psi(t)$, so it means that this I can rewrite as $0 - z(t)$ is nothing but $z(t)$, so I will rewrite $\phi(t) - \psi(t) < \epsilon$, whenever norm of $\phi(t_0) - \psi(t_0)$ is $< \delta$, so it means that for every $\epsilon > 0$ they exist a $\delta > 0$, such that norm of $\phi(t) - \psi(t) < \epsilon$, whenever norm of $\phi(t_0) - \psi(t_0)$ is $< \delta$, if we look at this carefully and if we take $\phi(t)$ as the fixed solution for which we are searching for the which; for which we are looking at the stability behaviour.

Then this simply says that for every $\epsilon > 0$, they exist a $\delta > 0$ such that and norm of $\phi(t) - \psi(t)$, where $\psi(t)$ is any solution of $\dot{x} = A$ of x is $< \epsilon$, whenever norm of $\phi(t_0) - \psi(t_0)$ is $< \delta$, so we can say that in this way $\phi(t)$; $x = \phi(t)$ is a stable solution, so this we are getting when we are assuming that 0 is a stable solution. So, this implies that if 0 is a stable solution then $\phi(t)$, where $\phi(t)$ is any fix solution of $\dot{x} = Ax$ is also a stable solution.

(Refer Slide Time: 11:35)

Now, we want to prove the other way round, we simply say that if 0 is unstable, if x identically = 0 is an unstable solution, then we want to prove that any solution let us say $\phi(t)$ is also unstable, so how we can look at; so if $x = 0$ is unstable solution, it means that they exist say, a solution $\phi(t)$

of $\dot{x} = A(x)$, such that the $\|h(t)\| < \delta$ for every $\epsilon > 0$ they exist a δ , I can find out that we have a solution $h(t)$ such that $\|h(t) - h(t_0)\| > \epsilon$ for every δ such that $\|h(t_0)\| < \delta$.

So, it means that for every δ , so for you can always find out one ϵ such that $\|h(t) - h(t_0)\| > \epsilon$, whatever δ I will choose, so it means that I can always, so it means that they exist an $\epsilon > 0$ such that $\|h(t) - h(t_0)\| > \epsilon$ for every δ such that $\|h(t_0)\| < \delta$, so it means that or we can write it like this that $h(t)$ is one such solution such that it is near to 0 at $t = t_0$.

So, at $t = t_0$, this norm of $h(t)$ is small, $\|h(t_0)\| < \delta$ but as t is $>$ say t_0 , then that norm of $h(t)$ is going to be bigger than some preassigned number, so it means that we can say that $h(t)$ is now moving away to this 0, right, so that is, what do you mean by unstable solution, now we want to show that this $\phi(t)$ is also unstable, for that we simply consider one solution $\psi(t)$ as $\phi(t) + h(t)$, which we have taken here.

So, if we take $\psi(t)$ and since $h(t)$ is one such solution and $\phi(t)$ is already we know, then $\psi(t)$ is one solution of $\dot{x} = Ax$ such that that norm of $\phi(t_0) - \psi(t_0)$ which is nothing but $h(t_0)$, we already know that this is $< \delta$ but this also implies that norm of $\phi(t) - \psi(t)$ which is nothing but norm of $h(t)$ and it is bigger than some ϵ , let us fix that ϵ . So, it means that if we take, let us call this as ϵ_0 here.

So, it means that they exist a $\epsilon_0 > 0$ such that $\|h(t_0)\| < \delta$ is true but norm of $h(t)$ is always bigger than this number ϵ_0 , so it means that if I take $\epsilon < \epsilon_0$ then the previous condition does not hold true, it means that for ϵ which is $< \epsilon_0$, I cannot find out any δ such that $\|z(t)\| < \epsilon$, whenever $\|z(t_0)\| < \delta$ because this norm of $h(t)$ is always bigger than this ϵ_0 , is that okay.

So, it means that for the same ϵ_0 , we can simply say that we can find out a solution $\psi(t)$ such that $\psi(t)$ which is given as $\phi(t) + h(t)$, it means that for this ϵ which is $< \epsilon_0$, I cannot find out any δ such that $\|h(t_0)\| < \delta$, implies that norm of $h(t)$ is $<$

epsilon, right because this norm of $\phi(t)$ is always bigger than this ϵ_0 , so it means that if zero solution is unstable solution, then this implies that $\phi(t)$ is also unstable solution.

And this is very, very important result in the sense that rather than checking the stability of any solution, we will just check the stability of only zero solution, right so it means that if we simply check the zero solution is stable, then we say that any solution is stable; and if a zero solution is unstable, then we simply say that any solution is unstable, so keeping this thing in mind let us consider the following theorem, which gives you a complete description of stability of zero solution or we can say the stability of any solution.

Because the stability of zero solution is equivalent to stability of any solution of $\dot{x} = Ax$, so now let us look at the theorem.

(Refer Slide Time: 17:06)

Theorem 1

(a) Every solution $x = \phi(t)$ of (1) is stable if all the eigenvalues of A have negative real part.

(b) Every solution $x = \phi(t)$ of (1) is unstable if at least one eigenvalue of A has positive real part.

(c) Suppose that all the eigenvalues of A have real part ≤ 0 and $\lambda_1 = i\sigma_1, \dots, \lambda_l = i\sigma_l$ have non zero real part. Let $\lambda_j = i\sigma_j$ have multiplicity k_j , i.e. the characteristic polynomial of A can be factored into the form

$$p(\lambda) = (\lambda - i\sigma_1)^{k_1} \dots (\lambda - i\sigma_l)^{k_l} q(\lambda)$$

Where all roots of $q(\lambda)$ have negative real part. Then, every solution $x = \phi(t)$ of (1) is stable if A has k_j linearly independent eigenvectors for each eigenvalue $\lambda_j = i\sigma_j$. Otherwise, every solution $\phi(t)$ is unstable.

$$AM(\lambda_j) = GIM(\lambda_j) \begin{matrix} v_j \\ \vdots \\ v_j \end{matrix} \neq GIM(\lambda_j) \begin{matrix} v_j \\ \vdots \\ v_j \end{matrix} \Rightarrow \Rightarrow$$

It says that every solution $x = \phi(t)$ of (1) is stable, if all the eigenvalues of A have negative real part and so, it means that if you calculate eigenvalues of A and it may be real, it may be complex but in any case, the negative; real part whether that is purely real or a complex value, if the real part for all the eigenvalues are negative, we simply say that solution is a stable, zero solution stable and hence any solution is a stable.

Second part of this theorem says that every solution $x = \phi(t)$ is unstable, if at least one eigenvalue of A has positive real part, so it means that if any of the eigenvalues of A have one positive real part, a positive real part then the solutions are all unstable, so all solutions are unstable solution, so the first part deals with the negative real part, if all these eigenvalues are having negative real part, it is done.

We have concluded that every solution is a stable solution, now the second part says that if at least one of the eigenvalues has positive real part then, all the solutions are unstable solution and the part C says that if we have some eigenvalues with 0 real part, then what we need to consider; so C part says that suppose that all the eigenvalues of A have real part ≤ 0 because if it is any of the eigenvalue has positive real part, it is all unstable.

So, there is no question arises when we have one Eigen value with positive real part, then we have one certain answer that it is unstable solution but if we have say consider that all the eigenvalues of A have nonnegative, sorry non-positive real part and let us say that we consider few eigenvalues with 0 real part, so let us say that $\lambda_1 = i\sigma_1$ and $\lambda_1 = -i\sigma_1$, these are some eigenvalues with nonzero real part, sorry, zero real part.

So, let $\lambda_j = i\sigma_j$ have multiplicity k_j so, in the case when real part is 0, then we have to look at the algebraic multiplicity or geometric multiplicity, so if we say that if algebraic multiplicity is k_j , it means that λ_j is repeated root of characteristic equation of multiplicity k_j and the characteristic polynomial of A can be factored into this form that $p(\lambda) = (\lambda - i\sigma_1)^{k_1} \dots (\lambda - i\sigma_l)^{k_l} q(\lambda)$, where $q(\lambda)$ has all the roots having negative real part, right.

Then, in this case every solution $x = \phi(t)$ is stable, if A has k_j linearly independent eigenvectors for each eigenvalue $\lambda_j = i\sigma_j$, otherwise every solution is unstable, so please try to understand here, in first part all the eigenvalues are negative right, so having negative real part, in second it is positive, at least one with positive real part. Now, consider equality one side, let us say equality is here.

Because if we have equality here, then we know that all solutions are unstable, so there is a possibility here that a solution may be stable, may not be stable, so here we consider the case when equality appears, so it means that they are eigenvalues for which we have zero real part okay, so now, let us say that λ_1 to λ_n are eigenvalues with 0 real part, then we have to look at the algebraic multiplicity of say λ_j and geometric multiplicity of λ_j , right.

If it is equal for each j , right then we say that solutions are stable solutions, otherwise solutions are unstable, so it means that if for all j , algebraic multiplicity of λ_j = geometric multiplicity of λ_j , then the solution is stable and if they exist $1j$ such that this is not equal, it means that $AM \lambda_j \neq GM$ of λ_j , then all the solutions are unstable solutions, so this is the content of this theorem.

In fact, here a stability of any solution $\dot{x} = Ax$ is now purely depending on the behaviour of eigenvalues of the coefficient matrix A , so that is; that gives a very, very important result in terms of the eigenvalues of the coefficient matrix. Now, let us try to prove this, so first let us prove the first part A that all the eigenvalues have negative real part.

(Refer Slide Time: 23:19)

Proof (a)

$\lambda = Ax$
 $x(t) = e^{At} \zeta$

Observe that every solution of (1), with initial condition $x(0) = \psi^0$ can be written in the form $\psi(t) = e^{At} \psi^0$.

Let $b_{ij}(t)$ be the ij element of the matrix e^{At} , and let $\psi_1^0, \dots, \psi_n^0$ be the components of ψ^0 . Then, the i th component of $\psi(t)$ is

$$\psi_i(t) = b_{i1}(t)\psi_1^0 + \dots + b_{in}(t)\psi_n^0 = \sum_{j=1}^n b_{ij}(t)\psi_j^0 \quad (2)$$

$$\begin{pmatrix} \psi_i(t) \\ \vdots \\ \psi_n(t) \end{pmatrix} = \begin{bmatrix} b_{i1}(t) & \dots & b_{in}(t) \\ \vdots & & \vdots \\ b_{n1}(t) & \dots & b_{nn}(t) \end{bmatrix} \begin{pmatrix} \psi_1^0 \\ \vdots \\ \psi_n^0 \end{pmatrix}$$

So, first thing we need to observe that every solution of 1 with initial condition $x(0) = \psi^0$ can be written as $\psi(t) = e^{At} \psi^0$ and this we can do in the sense that when we have a solution; differential equation $\dot{x} = Ax$, we already know that e^{At} is the power

e^{At} will serve as a fundamental matrix solution and any solution of this equation $\dot{x} = Ax$ can be written as $e^{At} * c$. Let us call this as $x(t)$.

So, $x(t)$ can be written as $e^{At} * c$, now depending on the initial condition we can fix this constant matrix that is c , so now we let us consider the initial condition $x(0) = \psi(0)$, then we can denote this particular form of the solution is given by $\psi(t)$, $\psi(t)$ is given by $e^{At} \psi(0)$. Now, any solution with the condition $x(0) = \psi(0)$ is having this form that $\psi(t) = e^{At} \psi(0)$.

Now, we want to look at how the stability of this $\psi(t)$ is depending on the eigenvalues; behaviour of the eigenvalues of A ; matrix A , so let $a_{ij}(t)$ be the ij element of the matrix, e^{At} , so we have e^{At} , e^{At} is like matrix of say solutions, it means that every column of e^{At} is a solution of $\dot{x} = Ax$, not only this that each column, I mean in fact x_1 to x_n 's are linearly independent solution of $\dot{x} = Ax$, okay.

Now, let us say that $\psi_1(0)$ to $\psi_n(0)$ be the component of $\psi(0)$, now we want to look at this $\psi(t) = e^{At} \psi(0)$ in terms of component, okay, so here let me write it, this is the matrix $a_{ij}(t)$ and $\psi(0)$ I am writing $\psi_1(0)$ to $\psi_n(0)$, so it is something like this, $b_{11}(t)$ to $b_{1n}(t)$ and here it is $b_{n1}(t)$ to $b_{nn}(t)$ and here we have $\psi_1(0)$ to $\psi_n(0)$, okay and this is your $\psi_1(t)$ to $\psi_n(t)$, so it means that if we looking at the i th component then I can write out $\psi_i(t)$ as i th row multiply by this.

It means that I can write $\psi_i(t)$ as $b_{i1}(t) * \psi_1(0) + b_{i2}(t) * \psi_2(0)$ and so on $b_{in}(t) \psi_n(0)$ or I can write it like this, $j = 1$ to n $b_{ij}(t) \psi_j(0)$.

(Refer Slide Time: 26:11)

Now as we have assume that all the eigenvalues of A have negative real part and let $-\alpha_1$ be the largest of the real part of the eigenvalues of A . It may be shown easily that for every number $-\alpha$, with $-\alpha_1 < -\alpha < 0$, we have a number K such that

$$|b_j(t)| \leq Ke^{-\alpha t} \quad t \geq 0.$$

p.w.

Therefore,

$$|\psi_j(t)| \leq \sum_{j=1}^n Ke^{-\alpha t} |\psi_j^0| = Ke^{-\alpha t} \sum_{j=1}^n |\psi_j^0|$$

for some positive constants K and α . Now, $|\psi_j^0| \leq \|\psi^0\|$.

Now, we already assume that all the eigenvalues of A have negative real part and hence we can find out the largest of the real part of the eigenvalues of A , so it means that suppose, negative real part means, suppose we have say, $\lambda_1 - \lambda_2$ and so on - λ_n , here I am assuming that λ_1 are positive, so we have these, you just arrange in this, so somewhere here it is 0 and some way here, we have λ_n and some way we have λ_1 .

So, let us look at the nearest to 0 that is call it $-\alpha_1$, denoted like $-\alpha_1$, so what; whoever be it may be anything, so let us say that $-\alpha_1$ is the largest of the real part of the eigenvalues of A , so it means that it may be real or it may be complex, just look at the real part of the eigenvalues of A and let us say this - λ_1 denote the real part of the eigenvalues λ_1 and let me uses some other notation.

Let us use λ_1 tilde, so these are the real part, we are looking at the real part, so let us say that $-\alpha_1$ be the largest of the real part of the eigenvalues of A , right or in terms of if you want to look at in terms of the absolute value, then look at the absolute value here, λ_1 tilde and λ_n tilde then this α_1 will be the smallest absolute value corresponding to this smallest absolute value of the real part of the eigenvalues of A .

So, now corresponding to this $-\alpha_1$, let us choose one more number say α such that $-\alpha_1 < -\alpha < 0$, right, so first thing is we have all the eigenvalues arrange it in this

manner, arrange the real part of eigenvalues in this manner and choose the greatest largest real negative real part as $-\alpha_1$ and corresponding to this $-\alpha_1$, find out one more number $-\alpha$ such that $-\alpha_1 < -\alpha < 0$.

So, here you choose somewhere here, your $-\alpha$, right, so it means that now corresponding to this $-\alpha$, our claim is that I can find out a number K such that $b_{ij} t \leq K e^{-\alpha t}$, for $t \geq 0$ that is very, very important observation in the sense. Now, if you look at that $e^{-\alpha t}$ is a matrix of this form, so it means that the first column is $b_{11} t, b_{21} t$ and so on up to $b_{n1} t$.

Now, it may happen that we have eigenvalues like we have n eigenvectors, then this is nothing but some constant time some $e^{-\lambda t}$ or $e^{\lambda t}$ but it may happen that we may not have n linear independent Eigen vectors then first or any of the column this of $e^{-\lambda t}$, may be say of this form like $q(t) e^{-\lambda t}$, let me write it like this, $q(t) e^{-\lambda t}$, where this $q(t)$ is a polynomial in terms of t and whose degree is at most $n-1$.

It cannot be more than $n-1$, so it means that the at most the degree of the polynomial is $n-1$ and $* e^{-\lambda t}$ and it is, it will achieve the degree $n-1$ in the case when we have only say, eigenvalues λ_i up to say repeated n times and for example, if you have say identity matrix, $1 \ 1 \ 1$, so in this case we have only one root that this 1 and it is repeated n times, in this case here it is diagnosable, it is quite obvious.

But if you look at the Jordan block corresponding to $1 \ 1$ of size n , then we can; we have only one Eigen vector, rest are all generalised Eigen vector and the solution will look like this.

(Refer Slide Time: 31:10)

$$e^{At} \left[\begin{matrix} (A-\lambda_i I)^0 v \\ (A-\lambda_i I)^1 v \\ \vdots \\ (A-\lambda_i I)^{n-1} v \end{matrix} \right]$$

$$x_i(t) = \frac{q_i(t)}{t} e^{\lambda_i t}$$

$\deg(q_i(t)) \leq n-1$
 $|q_i(t) e^{\lambda_i t}| \leq K e^{-\alpha t}$
 $\lim_{t \rightarrow \infty} \frac{|q_i(t) e^{\lambda_i t}|}{e^{\alpha t}} \rightarrow 0$
 $\Rightarrow \frac{|q_i(t) e^{(\lambda_i - \alpha)t}|}{e^{\alpha t}} \rightarrow 0$

$\lambda_i < -\alpha < 0$
 $\lambda_i - \alpha < 0$

Let me write it here, solution will look like what; solution corresponding to is looking like e to the power $\lambda_i t$ and here it is v that is Eigen vector $+ A - \lambda_i t * v$, I can write it v here, no problem, $+ A - \lambda_i$ square t square upon factorial 2, v and so on up to $A - \lambda_i$ power $n-1$ t to the power $n-1$ upon factorial $n-1$ v , right and this I am calling as, we can arrange this and I can write this as $q_i t e$ to the power $\lambda_i t$, we arrange; we rearrange in this manner.

And we can write it like $q_i t e$ to the power $\lambda_i t$, I can write it like this, so it means that each column, let me write it here $x_i t$ is of this form and maximum degree of this polynomial is going to be maximum $n-1$, so degree of q_i it is $\leq n-1$, okay so if it is happening and then we can say that $q_i t e$ to the power $\lambda_i t$ and it is less than I can write it $K e$ to the power $-\alpha t$, so our claim is that since it is true for see this α , $-\alpha$ is bigger than $-\alpha_1$.

So, my claim is that I can always write norm of e to the power $A t$ in fact, I can write it like this that norm of $b_{ij} t$ is $< K e$ to the power $-\alpha t$, so how I can write it here, my claim is that I can find out $1/K$ such that $q_i t e$ to the power $\lambda_i t$ modulus of this norm of this is $< K e$ to the power $-\alpha t$, so how we can say; this I can achieve like this that $q_i t e$ to the power $\lambda_i t$ divided by e to the power αt , right and take limit t tending to 0.

So, this I can write it here is equal to norm $q_i t e$ to the power, this will go, $\lambda_i - \alpha$ and it is tending to 0, sorry, t tending to infinity, now if you look at what is $\lambda_i - \alpha$; λ_i

It's are; if we are looking at the norm here, then it is \leq norm of q it \times norm of e to the power, in fact it is modulus of e to the power $\lambda_i - \alpha t$, right.

Now, here look at the sign of $\lambda_i - \alpha$ so, λ_i is $< -\alpha$ and it is $< -\alpha < 0$, so $\lambda_i - \alpha$ will be negative, right, so it means that if it is negative and t tending to infinity, this will go to 0 and since exponential function is dominating function over the polynomial, I will say that this limit will tend to 0 as t tending to infinity. So, if it is tending to infinity, I can always find out a function K such that norm of b it is $< K e$ to the power $-\alpha t$ that is what we have written here.

That b_{ijt} is $\leq K e$ to the power $-\alpha t$, $t \geq 0$, this we can always do this, let us again work on this and this is true, so you can consider this as an homework and let us relook it. Therefore, norm of ψ it is $\leq \sum_{j=1}^n$, now b_{ijt} is bounded by $K e$ to the power $-\alpha t$, so we are writing this as $K e$ to the power $-\alpha t$ norm of $\psi_j 0$ and this is $K e$ to the power $-\alpha t$ summation $j = 1$ to n $\psi_j 0$.

For some positive constant K and α , now we already know that this $\psi_j 0$ is \leq norm of $\psi 0$, here norm of $\psi 0$ is basically maximum of $\psi_j 0$, j is from 1 to n , so each one is \leq maximum of $\psi_j 0$, which I am denoting as $\psi_j 0$, so this is $\leq \psi$; each one is \leq norm of $\psi 0$.

(Refer Slide Time: 36:08)

Hence,

$$\begin{aligned} \|\psi_i(t)\| &= \max\{|\psi_1(t)|, \dots, |\psi_n(t)|\} \\ &\leq nKe^{-\alpha t} \|\psi^0\| \end{aligned}$$

Let $\epsilon > 0$ be given. Now we may choose $\delta(\epsilon) = \epsilon/nK$, so that $\|\psi_i(t)\| < \epsilon$ if $\|\psi^0\| < \delta(\epsilon)$ and $t \geq 0$, as

$$\|\psi_i(t)\| \leq nKe^{-\alpha t} \|\psi^0\| < nK\epsilon/nK = \epsilon. \quad (3)$$

Thus, the equilibrium solution $x(t) \equiv 0$ is stable.

So, in place of this I can write it here that norm of ψ_i is = maximum of ψ_1 to ψ_n and we already know that for each ψ_i , it is $< n$ times norm of ψ^0 $K e^{-\alpha t}$ and it is true for each i , so in particular the maximum will also be $< n K e^{-\alpha t}$ norm of ψ^0 , right. So, it means that ψ_i is $<$ this, now $e^{-\alpha t}$ is always < 1 , right, so I write this that norm of ψ_i is $\leq nK \cdot \delta$ norm of ψ^0 .

So, now you can choose δ , since δ we have to choose, so given any ϵ , we have to choose δ such that norm of ψ_i is $< \epsilon$, whenever $\|\psi^0\| < \delta$, so now choose δ as ϵ/nK right, so that norm of ψ_i is $< \epsilon$, if norm of ψ^0 is $< \delta$ at $t = 0$ here, t_0 I am choosing as 0 here, so it means that norm of ψ_i is $< \epsilon$, whenever norm of ψ^0 is $< \delta$.

And hence we can say that the equilibrium solution $x(t) \equiv 0$ is stable, so we have shown here that if all the eigenvalues have negative real part, then I can find out $-\alpha$ in a way such that norm of b_{ij} is $< K e^{-\alpha t}$ and with this we try to find out the bound of norm of ψ_i and hence we can show this thing that norm of ψ_i is $< \epsilon$, whenever norm of ψ^0 is $< \delta$.

And this shows that the zero solution is a stable solution and if zero solution is a stable, we have already shown that any solution of $\dot{x} = Ax$ is also stable and so it means that if all the

eigenvalues of A has negative real part, then zero solution is stable and hence every solution of $\dot{x} = Ax$ is a stable solution. So, with this I stop our discussion and in next lecture, we will discuss the; its second and third part.

And then we will also discuss some nonlinear system of differential equation and we will discuss the stability of solutions of nonlinear system, with this I stop, we will continue in next lecture, thank you very much for this.
