Lecture – 58
Stability for Discrete Systems

Dear students, welcome to this lecture on the stability of discrete systems, so in this lecture we will see some results on the stability of discrete system which are analogous to the stability of continuous dynamical systems.

(Refer Slide Time: 00:42)

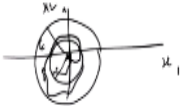

Stability

Consider 

$$x(k+1) = A(k)x(k)$$

$k = k_0, k_0+1, \dots$

It can be seen that $x(k) = 0$ for all k is the trivial or equivalent solution of (1).
 The trivial solution is said to be stable if for any given $\epsilon > 0$ there exists a $\delta > 0$ such that $\|x(k)\| < \epsilon$ whenever $\|x(k_0)\| < \delta$.
 The trivial solution is said to be asymptotically stable if it is stable and $x(k) \rightarrow 0$ as $k \rightarrow \infty$.
 Let $A(k) = A$ be a constant matrix and let $x(k_0) = x_0$ then the solution of (1) is

$$x(k) = A^{k-k_0} x_0$$

A is $n \times n$. $x(k) \in \mathbb{R}^n$ for $k \geq k_0$ (2)

$$\frac{dx}{dt} = A x(t)$$

$x(t) \equiv 0$ is trivial sol.
is equilibrium pt. (1)

So, earlier we have seen the continuous dynamical system of the form $dx/dt = A * x$ of t , where A is a constant n cross n matrix, so the result, the x of t identically $= 0$ is the trivial solution of this continuous system and it is also called the equilibrium point; equilibrium point of the dynamical system, so the stability of the system at this equilibrium point was analysed using the eigenvalues of the matrix A .

So, the result was if all the eigenvalues of A has negative real parts then, the system is asymptotically stable and if any of the Eigen value have negative real part, a positive real part then the system will be unstable and if or if the eigenvalues are purely imaginary in some cases, we can see that it will be stable, so there are some special condition on that particular case where the eigenvalues are imaginary.

So, depending on the algebraic and geometric multiplicities, we can decide the stability or instability of such systems, so here those results have been earlier seen while dealing with the continuous dynamical systems. So, analogous to those results we can see some result in the case of the discrete systems. So, let us consider the discrete system $x(k+1) = Ax(k)$ for various time instances we can let say $k = k_0, k_0 + 1$ etc.

And it can be easily seen, if $x(k) = 0$ for all k and if we substitute it in the right hand side, we will get $x(k+1)$ is also $= 0$, so we can conclude that the 0 ; $x(k)$ is identically $= 0$ for all k is a trivial solution of this system; system one or it can be called the equilibrium point, the origin is called the equilibrium point of this system. So, here A is a n cross n matrix and $x(k)$ belongs to \mathbb{R}^n for each value of k is the state variable.

Now, we will state the definition of the stability of the system at this equilibrium point, so here the trivial solution is said to be stable if for any given $\epsilon > 0$ there exist a δ positive such that whenever the initial condition $x(k_0)$ is $< \delta$, then the solution $x(k)$ lies within the ϵ neighbourhood, so here we see that if this is the state space for example, in the case of 2 dimension, let us say $x = x_1, x_2$, 2 variables are there.

Then for every given ϵ , 0 is the trivial solution, x_1 is 0 , x_2 is 0 is the trivial solution of the system then, for every given ϵ the radius of the circle is ϵ there exist a $\delta > 0$, we can find a circle of radius δ such that whenever the initial condition $x(k_0)$ is inside the δ circle, then the solution $x(k)$ for all the values of k , afterwards so that will always lie within the ϵ circle.

When we have take the discrete points because the solution is not a continuous one, $x(k_0)$ is x_0 is a point and then next point is $x(k_0 + 1)$ that will be a discrete point, so if you connect all the discrete points for each value of k , we will get a curve; we will get a discrete set of points all of them will lie within the ϵ circle, so that is the definition of the stability of the system. In addition to that stability, if you also have that $x(k)$ tends to 0 as, k tends to infinity.

So as, k becomes larger and larger, the initial point if you start, then for each value it will approach the origin, x of k_0 is starting point and x of $k_0 + 1$ k_0+2 etc., these point is finally reach the origin, in the limiting case as, k tends to infinity then we say that the system is asymptotically stable, so it is a similar definition that is the analogous to the continuous case. Now, we will see the condition on the stability, condition on the matrix for the stability of this discrete system.

So, let us consider instead of the time varying system A of k , let us consider A of k is a constant matrix A , then we have already seen in the previous lecture, the solution x of $k = A$ to the power $k - k_0 * x_0$.

(Refer Slide Time: 07:33)

Let $\lambda_j : j = 1, 2, \dots, n$ be given eigenvalues of A . If A is diagonalizable then we can find n linearly independent eigenvectors $x_j : j = 1, 2, \dots, n$ such that

$$Ax_j = \lambda_j x_j, j = 1, 2, \dots, n.$$

and $A^m x_j = \lambda_j^m x_j$ (3)

for any +ve integer m .

As the eigenvalues $\{x_1, x_2, \dots, x_n\}$ forms a basis of R^n , the initial vector x_0 can be expressed as

$$x_0 = c_1 x_1 + c_2 x_2 + \dots + c_n x_n$$

(4)

So, let $\lambda_j ; j = 1$ to n be the eigenvalues of the matrix A , so if A is diagonalisable, then we can find n linearly independent eigenvectors corresponding to these eigenvalues λ_j , so let us say x_1, x_2, x_n are the n linearly independent eigenvectors which satisfy the equation like this, $Ax_i = \lambda_j x_i$ for $i = 1$ to n standard definition of eigenvalues and eigenvectors, then multiplying repeatedly, we can easily see that A power m $x_i = \lambda_j$ to the power $m * x_i$ for $i = 1, 2$ up to n .

So, this is for any positive integer m satisfies and because we have n linearly independent vectors in R^n , it will form a basis in R^n , so any vector can be written as a unique linear combination of

the eigenvectors, so initial condition x_0 is a vector in \mathbb{R}^n , so it can be written as $c_1x_1 + c_2x_2$ etc. c_nx_n as given in equation 4.

(Refer Slide Time: 09:04)

$A^m x_i = \lambda_i^m x_i$

\therefore from (2)

$$x(k) = c_1 \lambda_1^{k-k_0} x_1 + c_2 \lambda_2^{k-k_0} x_2 + \dots + c_n \lambda_n^{k-k_0} x_n \quad (5)$$

Note that $k - k_0 \geq 0$.

From (5) we can see that if $|\lambda_i| > 1$ for some i then $x(k) \rightarrow \infty$ as $k \rightarrow \infty$ and if $|\lambda_i| \leq 1$ for all $i = 1, 2, \dots, n$ then $\|x(k)\|$ is bounded for all k which implies stability.

If $|\lambda_i| < 1$ for all $i = 1, 2, \dots, n$ then $x(k) \rightarrow 0$ as $k \rightarrow \infty$ which implies asymptotically stability.

$|\lambda_i| \rightarrow 0$ as $m \rightarrow \infty$ if $|\lambda_i| < 1$.

So, substituting that initial condition in the expression 2 that is x of k is A to the power $k - k_0 * x_0$, so in the place of x_0 , if you substitute equation 4, we get the expression like this because A power $m x_i = \lambda_i$ to the power $m x_i$, so we can substitute using this, we get the expression x of k to be like, now we take k larger because we are interested in k tending to infinity, so we take k is $> k_0$ and further it tends to infinity.

And when we have $k - k_0$ always positive and if the eigenvalues are such that modulus of λ_i is > 1 , even if one of the eigenvalue have modulus > 1 , we can easily see that it will tend to infinity λ_i for example, if λ_1 is > 1 , then its positive power will keep increasing and then it will tend to infinity, it implies that x of k will tend to infinity, as k tends to infinity.

So, for the stability condition we need that the modulus of the eigenvalue λ_i all of them has to be ≤ 1 , so if the modulus is < 1 , strictly < 1 , we can easily see that the modulus of λ_i to the power any positive number, it will tend to 0 as m tends to infinity, if this is < 1 , strictly < 1 , so we can see that if all the eigenvalues have the modulus strictly < 1 or if they lie within the unit circle.

If we take the unit circle in the complex plane and if all the eigenvalues lie within the unit circle then we say that the system is asymptotically stable and if the modulus of any of the eigenvalues = 1, we can see that this particular term is always a constant, if we take modulus here and then if the modulus = 1, a particular term is constant and if the remaining eigenvalues are inside the unit circle, the remaining terms will tend to 0.

So, we can say that the modulus of x of k , it may not converge to 0 but it will remain a bounded value because C_1 is; C_1, C_2, C_N are bounded values, so modulus of x of k will be bounded provided the modulus of λ_i or any some of the modulus of the eigenvalues are 1, so in that case we say that it is stable here.

(Refer Slide Time: 12:38)

o

In case A is not diagonalizable then with suitable modification in the above discussion the stability result can be proved.

So, similarly in the case that A is not diagonalisable we will get the Jordan canonical form, so in that case instead of n linearly independent eigenvectors here, in the diagonalisation case, we will get n linearly independent eigenvectors but in the case of the non-diagonalisable matrix, we will get the linearly independent eigenvectors, the number of linearly independent eigenvectors will be strictly $< n$.

So, we will be able to find the generalised eigenvectors and then we get a basis consisting of eigenvectors and generalised eigenvectors in the space \mathbb{R}^n , then the initial condition can be

written as the linear combination of eigenvectors and the generalised eigenvectors and the proof will be similar, once we write the solution x of k in the form of equation 5 using eigenvectors as well as generalised eigenvectors.

Then, we will get the similar result that if all the eigenvalues lie within the unit circle, it will be an asymptotically stable and if any of the eigenvalue lie outside the unit circle, it will be unstable etc. so this result is similar.

(Refer Slide Time: 14:18)

Stabilizing using feedback

Consider the linear dynamical system

$$x(k+1) = Ax(k) \quad (6)$$

and the control system

$$x(k+1) = Ax(k) + Bu(k) \quad (7)$$

If the system (6) is not stable then by adding a suitable control term $Bu(k)$ and choosing a suitable feedback control $u(k)$ system (7) can be made stable at the trivial solution.

$$x(k) \rightarrow 0 \text{ as } k \rightarrow \infty$$

Now, stabilising using feedback, so let us consider the dynamical system given in equation 6 here, if the matrix A is such that the eigenvalue, some of the eigenvalue lie outside the unit circle, then the system is unstable now, in order to make the system stable by applying a control term, so we can consider the control system x of $k+1$ is $A * x$ of $k + B * u$ of k , where u of k is the control variable for various values of k , k is initial condition is k_0 $k_0 + 1$ etc.

Now, in order to make the system say asymptotically stable, so we want that x of k should tend to 0 as k tends to infinity is the requirement for asymptotically stable system, we have to select the control u of k in a special manner, so that the system becomes stable or asymptotically stable.

(Refer Slide Time: 15:52)

$$u(k) = \begin{pmatrix} K \\ m \times n \end{pmatrix} \begin{pmatrix} x(k) \\ n \times 1 \end{pmatrix}$$

If A and B satisfy the controllable property i.e. $\text{rank}[B \ A \ B A^2 B \dots \ A^{n-1} B] = n$ then we can find a matrix K such that $A + BK$ has all eigenvalues within the unit circle so that the system (7) is stabilized using the feedback control $u(k) = Kx(k)$.

$$x(k+1) = A x(k) + B u(k)$$

$$= (A + B K) x(k)$$

To find K such that $A + B K$ has eigenvalues in unit circle.

So, this procedure is again similar to that of the continuous case as we have seen in the feedback control lecture that we can find a feedback control u of k such that u of small k , it is some matrix K times x of k , where k ; this is a m cross 1 matrix and this is n cross 1 matrix, so we will get m cross n matrix, the k matrix is m cross n and so we have to find a m cross n matrix K such that $A + BK$ has all the eigenvalues within the unit circle.

So that the resulting system x of $k + 1$ is; so, x of $k + 1$ is Ax of $k + Bu$ of k and if you substitute u of k to be K times; capital K times x of k , so we get a simple system like this and if the all the eigenvalues of $A + BK$ has a modulus < 1 or they lie within the unit circle, then we can say that the system is stabilised, in that case x of k will converge to 0 as, k tends to infinity and the procedure is exactly similar to the case of continuous system which we have seen in the feedback control.

(Refer Slide Time: 17:53)

Lyapunov Stability Theory

Consider the system

$$x(k+1) = f(k, x(k))$$

where f is function such that $f(k, 0) = 0$ for all k .
Then $x(k) = 0$ for all k is an equilibrium/trivial solution of (8).

$\frac{dx}{dt} = f(x(t))$
 $f(0) = 0$ is equilibrium
 $\Rightarrow x=0$ (8)

Lyapunov Function

A functional $V(x(k))$ is called a Lyapunov function if for some $r > 0$ $V(x(k)) > 0$ and $V(0) = 0$ for any sequence $x(k)$ such that $\|x(k)\| < r$.

Now, another analogous theory that is we have seen the Lyapunov stability theory for the continuous system and if you have $dx/dt = f$ of x of t , where f of $0 = 0$, f is a non-linear function such that f of $0 = 0$, this will imply that $x = 0$ is equilibrium point of the given continuous system, so to analyse the stability of the system at this equilibrium point, we have seen the Lyapunov theory that is if there exist a Lyapunov function V that is v is a positive definite function that is V of x is strictly positive for all x non-zero and V of $0 = 0$.

And the derivative of V with respect to is negative definite, then the system is asymptotically stable, so that was the Lyapunov stability theorem for asymptotically stability and if dV/dt is negative semi-definite, then the system is stable, so this result we have seen in the stability lectures. Now, we will see a similar result for the discrete system, so a function V of x of k is called the Lyapunov function, if for some $r > 0$, the radius $r > 0$, V of x of k is > 0 .

And V of $0 = 0$ for any sequence x of k within this circle of radius r , so let us for simplicity assume that the vector x is in r_2 , x is x_1, x_2 , x of k is x_1 of k, x_2 of k , so these are the; this is a state space now, if you take your radius r , a circle of radius r and if x is within this circle x of k , then V of x of k , so we will get the surface, x_1, x_2 is this and then the value of the V ; V of x of k , so if the radius of the circle is r in the $x_1 x_2$ plane.

Then corresponding to each value of x_1 x_2 within this circle, we will have a positive definite function so which represent the surface V of x_1 x_2 , the surface is given by $V = V$ of x_1 x_2 .

(Refer Slide Time: 21:41)

$x(k+1) = f(k, x(k))$
Non-autonomous

Now consider the autonomous system

$$x(k+1) = f(x(k)); f(0) = 0 \quad (9)$$

Theorem

System (9) is stable at the trivial solution if there exists a Lyapunov function $V(x(k))$ such that

in (v) and (u) of V

$$\Delta V(x(k)) = V(x(k+1)) - V(x(k)) \leq 0$$

for any sequence $x(k)$.

The trivial solution is asymptotically stable if $\Delta V(x(k)) < 0$ for any sequence $x(k)$.

Within the circle of radius r , so if there exist a r satisfying this condition, we say that it is a Lyapunov function and will see the result on the stability of the system, autonomous system, so if we consider x of $k + 1$ is a non-linear function k and x of k , then it is called time varying system that is non-autonomous system and so, this is non-autonomous and because k is appearing explicitly in this equation.

And if you have the equation like 9, x of $k + 1$ is f of x of k , where k does not appear explicitly but it can appear in as a part of x of k , then it is called the autonomous system, so the system here 9, actually it is 9, the system 9 is stable if the trivial solution, the system 9 is stable at the trivial solution, if there exist a Lyapunov function as defined earlier and ΔV of x of k that is the increment; increment of the function V , okay at x of k .

So that is given by V at x of $k + 1 - V$ at k , the increment if it is ≤ 0 , in other words V is a decreasing function with respect to the variable k here, so if this happens then we say that the trivial solution is asymptotically stable and if it is ≤ 0 then, it is a system is stable, so it is analogous to the continuous case, in the place negative semi-definite, we have that the increment is ≤ 0 .

And in the place of negative definite, negative definiteness of the function V , we have the increment is strictly < 0 for any sequence, so basically both of the conditions are very much similar to that of the continuous case so similarly, the proof is; proof of this Lyapunov theory is exactly similar to that of the continuous case, only thing is in the continuous case, we will have the continuous function x of t .

And in the discrete case, we have the discrete sequence, the points x of k at discrete points, so the result is similar, the proof is also similar here.

(Refer Slide Time: 25:04)

Example

$$\begin{aligned}
 x_1(k+1) &= -x_1(k) + x_1(k)x_2^2(k) \\
 x_2(k+1) &= x_2(k)x_1^2(k) - x_2(k)
 \end{aligned}$$

$(x_1(k), x_2(k)) = (0, 0)$ is the trivial solution *e qulibrium - ut*
 Let $V(x(k)) = V(x_1(k), x_2(k)) = x_1^2(k) + x_2^2(k)$

$$\begin{aligned}
 \Delta V(x(k)) &= x_1^2(k+1) + x_2^2(k+1) - x_1^2(k) - x_2^2(k) \\
 &= \underbrace{\left(-x_1(k) + x_1(k)x_2^2(k)\right)^2 + \left(x_2(k)x_1^2(k) - x_2(k)\right)^2 - x_1^2(k) - x_2^2(k)}
 \end{aligned}$$

So, now let us see a simple example to illustrate the theory, consider this system $x_1(k+1) = -x_1(k) + x_1(k)x_2^2(k)$ and $x_2(k+1) = x_2(k)x_1^2(k) - x_2(k)$ for various values of k , integer values of k and it can easily be seen that when x_1 and x_2 both are 0, then it satisfies this equation, therefore $(0, 0)$ is the trivial solution or the equilibrium point of the system. So, if we consider the Lyapunov function, V of x of k that is V of x_1, x_2 is $x_1^2 + x_2^2$ for each value of k .

Then it is easy to see that it is positive definite strictly > 0 if x_1, x_2 is not the origin and at the origin, it is 0 value and the increment ΔV of x of k , if you substitute directly that is V of x of $k+1$ is $x_1^2(k+1) + x_2^2(k+1) - V$ of x of k is $x_1^2(k) + x_2^2(k) - x_1^2(k) - x_2^2(k)$, so this

expression from the given equation if you substitute for $x_1(k+1)$ and $x_2(k+1)$, we get this expression.

(Refer Slide Time: 26:58)

$$\begin{aligned}
 &= -2x_1^2(k)x_2^2(k) + x_1^2(k)x_2^4(k) - 2x_1^2(k)x_2^2(k) + x_1^4(k)x_2^2(k) \\
 &= -x_1^2(k)x_2^2(k)(2 - x_2^2(k)) - x_1^2(k)x_2^2(k)(2 - x_1^2(k)) < 0
 \end{aligned}$$

$\therefore \Delta V(x(k)) < 0$ if $x_1^2(k) + x_2^2(k) < 2$.
 \Rightarrow asymptotic stable.

$x_2^2 < 2$
 $x_1^2 < 2$

And further by simplifying, we get ΔV of x_1, x_2 is strictly < 0 , provided these quantities are positive that is $x_2^2 < 2$ and $x_1^2 < 2$, then we will get strictly < 0 sign or in other words, if x_1 and x_2 lies within the circle of radius 2, then also we can say that the right hand side is strictly < 0 , so according to the definition, the value r , we have seen that if there exist a circle of radius r in which this conditions are satisfied.

Then, the system is asymptotically stable, so this illustrate the asymptotically stability of this the Lyapunov theory, okay, so with this we conclude the stability concept for the time invariant system for the discrete dynamical system, okay, thank you.
