Near-Wall Turbulent Flows-01

In the previous two lectures, we considered the formal aspect of turbulence and asked a question how turbulence sustains itself. We showed this process of sustenance through breakdown of vortices. We explained this process in three ways; one was scale analysis, second was spectral analysis and the third was the vorticity dynamics. Now, we must turn to more predictive aspects, after all we wish to - we were able to compute or calculate friction factor and Nusselt numbers in turbulent flows.

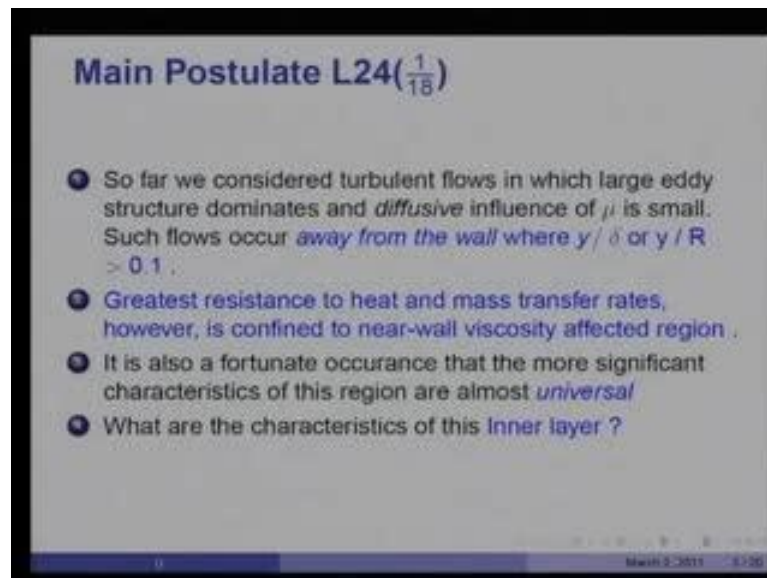

(Refer Slide Time: 01:07)

So, I am going to turn today to regions of flow close to the wall. If one analyses experimentally, then one would find an inner layer, as well as an outer layer. There are some special features of this inner layer, which make it possible for us to determine the

friction factor and Nusselt number. I will also ensure how Prandtl's mixing length idea can be employed to predict velocity distribution in inner layer.

(Refer Slide Time: 01:56)

So, let us turn to the main postulates. So, in our formal aspect, we dealt with turbulent flows, whose structure is dominated by large eddies that is where the production takes place. The diffusive influence of viscosity was rather small, being confined only to carry out dissipation at the smallest scales. Near the wall, however, viscosity also plays its role in bringing about diffusion. What is the size of this inner layer? To begin with, let me say, approximately y divided by δ in a boundary layer would be of the order of 15 percent. Likewise, y divided by radius, where y distance from the wall in a pipe flow would again be of the order of 15 percent.

So, we are talking about a fairly narrow region close to the wall, about 15 percent; whereas, away from the wall, where diffusive influence of viscosity is very small, would be greater than 0.15. However, it is the inner region, which is of great importance to us; because, the greatest resistance to heat and mass transfer occurs close to the wall, where or in the region, in which, viscosity play this dominant role; that is where the fluid flow is sluggish. Therefore, likewise, the heat and mass transfer is also very sluggish. Therefore, we are very much interested in this inner region.

Now, it is of course a very fortunate occurrence - quite an accident of nature, really; that the most significant characteristics of this inner region are almost universal. We are going to exploit this universality of the inner layer to predict friction factor Nusselt number.

(Refer Slide Time: 04:08)

Law of the wall - 1 - L24($\frac{2}{18}$)

The Inner layer $y/\delta \approx 0.15$ comprises 3 layers

- 1 Laminar-like **viscous sub-layer**. In reality, this layer is characterised by a repeated but infrequent fluid bursts.
- 2 Next, the **transition layer** - Phenomenologically, likened to the inertial sub-range of the energy spectrum
- 3 Next, the **inner turbulent layer**

Phenomenologically,

$$u = F(y, \tau_w, \mu, \rho, \text{others})$$

where *others* include parameters - BL thickness δ (or radius R), dp/dx , v_w , wall roughness height y_r .

So, let us ask a question what are the characteristics of this inner layer? This is the flow against a wall, this is the free stream velocity U_∞ and this is the total boundary layer thickness δ , let us say.

Then, the inner layer which as I said is about 15 percent of the total, itself comprises of three characteristic layers, as I shown here. The inner most layers is often called the viscous sub-layer, is almost laminar-like, because that is where the effect of viscosity is so great that all fluctuations are almost killed and you get essentially laminar flow.

In reality, however, this layer is characterized by repeated but infrequent fluid burst. What happens is, the laminar sub layer here grows a little, becomes unstable and weak. At this point, lumps of fluid from the outer layer hit the inner viscous sub-layer and uproot fluid out into the outer layer again or the outer parts of the inner layer. This kind of fluid being flung out from the sub layer is quite visible, if you did flow visualization of a typical turbulent boundary layer.

Then, this region is very intermittent. When I say it is intermittent, it is infrequent. So, for all practical purposes to begin with, we might say the region is almost like laminar layer.

The next is the transitional layer, which we may likened to the inertial sub range that we identified during our formula aspects of turbulence; that is called the transitional layer. Now, here, at both turbulent fluctuations, as well as fluid viscosity, both are equally dominant. Then, there is the fully turbulent part of the inner layer, where essentially the flow is very much like fully turbulent flow.

So, as I said, inner layer has three layers; laminar sub layer, transitional layer and the inner turbulent layer. The outer layer is definitely turbulent, so we will take up the outer layer towards the end of this lecture. But, presently we wish to concentrate on the inner layer, because in this part of the boundary layer that really offers significant **rates** resistances to heat transfer. It is also the region in which greater part of the temperature velocity and concentration gradients take place, whereas the outer part has more or less uniform profiles. So, it is the inner layer which is of great importance to us.

Now, **phenomenologically** I may postulate that the velocity parallel to the wall u would be function; first of all of the fluid property - two properties being used; ρ , the density and viscosity. Of course, u must vary with distance from the wall, therefore y is included. τ_{wall} would determine the shear stress at the wall that is the velocity gradient at the wall. Because, τ_{wall} is $\mu \frac{du}{dy}$ at y equal to 0, therefore shear stress is also included here. Then, there are many other factors that are likely to influence the velocity profile in the inner layer.

Now, what are those other factors? The other factors would be the boundary layer thickness; itself could well influence the nature of the velocity of the profile. The pressure gradient and its variation in the x direction could also affect velocity distribution. If there is transpiration or mass transfer, then of course, v_w will also influence the velocity distribution. Finally, in order to enhance the rate of heat transfer, particularly in gases, we often employ rough surfaces, so even the roughness height would influence the nature of the velocity profile in this.

(Refer Slide Time: 08:54)

Law of the wall - 2 - L24($\frac{3}{18}$)

- Experimental evidence, however, shows that for a smooth, impermeable surface the inner layer is almost completely free of all the *other* parameters.
- Independence from δ suggests that no information travels from the outer parts to the inner region.
- Independence from dp/dx suggests that the inner region is independent of the *history* of the flow except that τ_w may depend on the upstream events. The structure of turbulence is thus presumed to be in *local equilibrium*; that is, the timescale of the eddies \ll the time taken by the mean flow to change its structure appreciably in response to dp/dx .
- This assumption of *local equilibrium* is valid for adverse and mildly favourable dp/dx , but not when *re-laminarisation* is encountered in highly accelerated BLs ($\nu/U_\tau^2 \cdot dU_\tau/dx > 3 \times 10^{-6}$).

Experimental evidence, however, shows that for a smooth, impermeable surface; smooth meaning roughness height is 0; impermeable means v_w is 0; the inner layer is almost completely free of all other parameters. Now, this is very interesting that for v_w equal to 0, for a smooth surface, the other parameters play a very minor role. I will explain why it is so.

So, for example, independence from δ suggests that no information travels from the outer parts to the inner regions. So, inner region is sort of insular region that is not really effected by what happens very far outside into the outer layers. Independence from dp/dx suggest that the inner region is also independent of the history of the flow. Except that the shear stress variation along the wall, may influence a little bit the velocity profile, but the influence would be expected to be not so great, as far as the velocity profile is concerned.

Structure of turbulence is thus presumed to be in local equilibrium; that is, the time scale of eddies in the inner layer are much smaller than the time taken by the mean flow to change its structure appreciably in response to dp/dx .

You may like to think about this. I often give the example of a city and a village. A city quickly response to what happens in distant places; for example, Bombay would get influenced by what happens in New York or London, but a village, say 100 kilometers

outside Mumbai, would be hardly influenced by what happens in the world around. I am using an analogy, so that you might remember what we mean by insularity of the inner region and the slowness of the inner region.

This assumption of local equilibrium is valid for adverse, as well as mildly favorable dp/dx , but not when re-laminarisation is encountered at very high accelerated boundary layers. Of course, we are talking about here fairly moderate range of plus and minus pressure gradients. So, highly accelerated boundary layers, this pressure gradient parameter $\mu \nu$ by U infinity square dU infinity by dx would be greater than 3 into 10 raise to minus 6.

So, we are not talking about such highly accelerated boundary layer, we are talking about only those which are more frequently encountered, having moderate plus and minus pressure gradients.

(Refer Slide Time: 11:50)

Law of the wall - 3 - L24($\frac{4}{18}$)

μ and y are relevant because at the wall, $\tau_w = \mu \partial u / \partial y$, ρ is included due to the importance of momentum transfer resulting from velocity fluctuations in the transition and the fully turbulent layers. Therefore, dimensional analysis gives

$$\frac{\rho u^2}{\tau_w} = F\left(\frac{\rho y^2 \tau_w}{\mu^2}\right) \quad \text{Define}$$

$$u_* \equiv \sqrt{\tau_w / \rho} \quad (\text{Friction velocity}) \quad u^+ \equiv \frac{u}{u_*} \quad y^+ \equiv \frac{y u_*}{\nu}$$

or $u^+ = F(y^+)$ (universal 'law of the wall')

We now seek form of $F(y^+)$ in three parts of the inner layer.

We included viscosity and distance from the y , simply because, as I said, τ_w is equal to $\mu du/dy$, therefore, we must include μ and y . The density ρ is included due to the importance of momentum transfer resulting from velocity fluctuations, in the transition and fully turbulent layers.

As I said, there are bursts of fluid, which come in breakdown of the laminar sub layer and there is a burst of fluid coming out of the laminar sub layer. This requires

momentum transfer from the outer layers to inner layer, of the inner layers. Therefore, density would definitely play an important role. Therefore, we have included density.

So, if I were to go back to these slides (Refer Slide Time: 04:08). So, we are essentially excluded all others and only we are going to concentrate on these four parameters, because they define more or less the equilibrium of the inner layer. So, if I were to carry out the dimensional analysis, I would find that ρu^2 divided by τ_{wall} would be function of $\rho y^2 \tau_{wall}$ by μ^2 .

Now, I define u^+ equal to $\sqrt{\tau_{wall} / \rho}$; this is often called the friction velocity; square root of τ_{wall} by ρ has the dimensions of velocity. I will define a dimensionless velocity u^+ as u divided by u^+ and y^+ would be defined as $y u^+$ divided by ν . You can see this is a kind of a Reynolds number, based on distance from the wall and the friction velocity - y^+ . So, both u^+ and y^+ are dimensionless, so you will readily recognize that this is nothing but $u^+{}^2$ and this is nothing but $y^+{}^2$ or another way of saying is, u^+ will be a function of $y^+{}^2$. At least, the phenomenology suggests that this relationship will be universal and it is often called the universal law of the wall.

The exact forms of $F(y^+)$, we must now find out, what the form it will take in the three layers; that is, the laminar sub layer, the transitional layer and the fully turbulent layer of the inner turbulent layer.

(Refer Slide Time: 14:23)

Variation of shear stress - L24($\frac{5}{18}$)
 In the inner layer, the BL form of RANS eqn will read as

$$\rho \left[u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} \right] = - \frac{d p}{d x} + \frac{\partial \tau_{tot}}{\partial y} - \rho \left[\frac{\partial}{\partial x} (\overline{u^2} - \overline{v^2}) \right]$$

$$\tau_{tot} = \tau_l + \tau_t = \mu \frac{\partial u}{\partial y} - \rho \overline{u'v'}$$

The terms in sq brackets on RHS are important only in highly accelerated flows - hence ignored. Then, since $u (\partial u / \partial x) \approx 0$ and $v \approx v_w$,

$$\frac{\partial \tau_{tot}}{\partial y} \approx \frac{d p}{d x} + \rho v_w \frac{\partial u}{\partial y} \rightarrow \text{intergration gives}$$

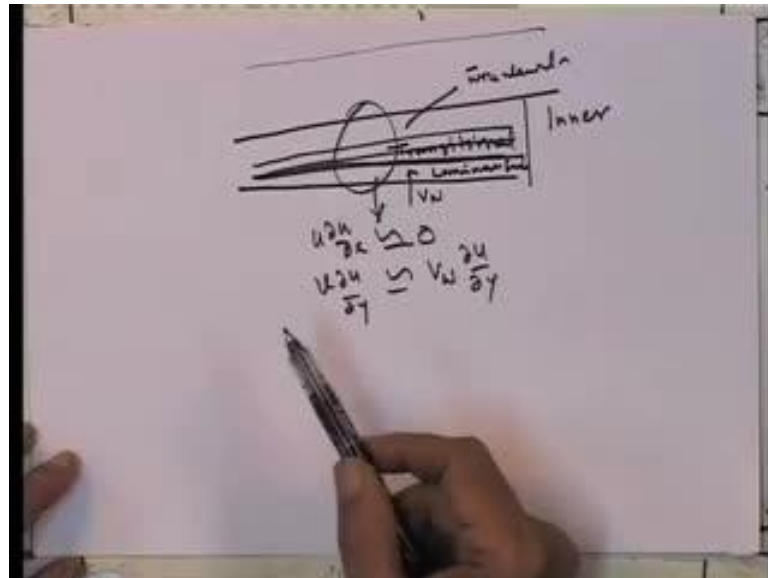

$$\frac{\tau_{tot}}{\tau_w} = 1 + \frac{y}{\tau_w} \frac{d p}{d x} + \frac{\rho v_w u}{\tau_w} = 1 + \rho^+ y^+ + v_w^+ u^+$$

$$\rho^+ = \frac{\nu}{\rho u_\tau^2} \frac{d p}{d x} \quad v_w^+ = \frac{v_w}{u_\tau} \quad (\text{Definitions})$$

So, let us go layer by layer. To do that you will recall that the RANS equations for actual momentum would look like this; these are the convection terms; this is the pressure gradient term; this is the total shear stress. There would be these terms, which would arise only which are necessary to be included, only when highly accelerated flows are considered.

But, as I said, we are not going to consider, so those terms will be dropped. Also, very close to the wall, u is very very small in the inner layer, which is about 15 percent. u by du dx would be much much smaller than this quantity v du by dy. Therefore, this term can also be dropped; as a result what we will get is, d tau tot total divided by dy would be approximately equal to d p by d x plus rho v w du by dy.

(Refer Slide Time: 15:34)

Now, of course, v equals v_w ; this is the inner layer; v_w is present only here; this is the turbulent layer, sorry; this is the transitional layer; this is the laminar sub layer. So, we say that $u \frac{du}{dx}$ will be approximately 0 in these region. $v \frac{du}{dy}$ would be approximately equal to $v_w \frac{du}{dy}$, these are very very approximate in the sense that v_w extends its effect in the inner 15 percent of the total boundary layer thickness.

(Refer Slide Time: 16:36)

Variation of shear stress - L24($\frac{5}{18}$)
 In the inner layer, the BL form of RANS eqn will read as

$$\rho \left[u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} \right] = - \frac{dp}{dx} + \frac{\partial \tau_{tot}}{\partial y} - \rho \left[\frac{\partial}{\partial x} (\overline{u^2} - \overline{v^2}) \right]$$

$$\tau_{tot} = \tau_t + \tau_l = \mu \frac{\partial u}{\partial y} - \rho \overline{u'v'}$$

The terms in sq brackets on RHS are important only in highly accelerated flows - hence ignored. Then, since $u (\partial u / \partial x) \approx 0$ and $v \approx v_w$,

$$\frac{\partial \tau_{tot}}{\partial y} \approx \frac{dp}{dx} + \rho v_w \frac{\partial u}{\partial y} \rightarrow \text{intergration gives}$$

$$\frac{\tau_{tot}}{\tau_w} = 1 + \frac{y}{\tau_w} \frac{dp}{dx} + \frac{\rho v_w u}{\tau_w} = 1 + p^+ y^+ + v_w^+ u^+$$

$$p^+ = \frac{v}{\rho u^2} \frac{dp}{dx} \quad v_w^+ = \frac{v_w}{u} \quad (\text{Definitions})$$

March 3, 2011 7:20

If I make these assumptions, then you will see that I can non dimensionalize this. First of all I must integrate this, so tau tot would be d p d x into y plus rho v w into u and tau tot would be equal to tau wall at y equal to 0.

So, in other words, this integration would result into tau tot divided by tau wall equal to 1 plus y divided by tau wall d p by d x plus rho v w u divided by tau wall. Now, you can see, this is nothing but, this is tau wall divided by rho. Here, in the denominator, which is u tau square; so I can form a v w plus, which is v w over u tau. u over u tau will give me u plus, so this v plus u plus.

I will define this term as p plus y plus, in which case, p plus would be defined in this fashion, nu divided by rho u tau cube dp by dx; v w plus would be v w by u tau; these are the definitions.

(Refer Slide Time: 18:12)

Forms of $F(y^+)$ - 1 - L24($\frac{6}{18}$)

To begin with, we assume that $dp/dx = v_w = 0$. Then, $\tau_{tot} = \tau_w = \text{const}$. Hence,

- ① In Laminar sub layer $\tau_{tot} = \tau_w = \tau_i = \mu \partial u / \partial y$ or, upon integration, $u = (\tau_w y) / \mu + C$ where $C = 0$ since, $u = 0$ at $y = 0$. Hence, rearrangement gives $u/u_w = y u_w / \nu$ or, $u^+ = y^+$.
- ② When dp/dx is moderate, eqn for $\partial \tau_{tot} / \partial y$ shows that 2nd and 3rd derivatives of u w.r.t. y will be nearly zero. Hence, expanding in Taylor's series about $y^+ = 0$, yields:

$$u^+ = y^+ + \frac{y^{+4}}{4!} \frac{\partial^4 u}{\partial y^{+4}} + \dots$$

- ③ This equation shows that for small values of y^+ , equation $u^+ = y^+$ holds; but at some critical distance away from the wall, u^+ must abruptly depart from linearity.

So, hold this in your mind that the ratio of shear stress - a total stress to the shear stress at the wall is 1 plus pressure gradient times y by tau wall and rho v w u by tau wall. So, in effect, this ratio is in fact influenced by the pressure gradient, as well as the effect of v w, as it should be.

(Refer Slide Time: 18:39)

Handwritten derivation on a whiteboard:

$$\tau_{tot} = \tau = \tau_1 + \tau_t = \mu \frac{du}{dy} \quad \text{at } y=0$$

$$u = \frac{\tau_w}{\mu} y + C \quad \text{at } y=0, u=0 \therefore C=0$$

$$u = \frac{\tau_w}{\mu} y$$

$$\frac{u}{u_{\tau}} = \frac{u_{\tau}^2}{u_{\tau}} \frac{y}{\nu} = \frac{y u_{\tau}}{\nu}$$

$$\underline{u^+ = \beta y^+} \quad \text{in LSL}$$

So, now, let us look at layer by layer. To begin with, we shall assume that dp by dx and v and w are both 0; that means, we are considering the case in which this is 0 and this is 0, so τ_{tot} would be equal to τ_{wall} throughout the inner layer; therefore, shear stress is a constant. Now, in the laminar sub layer, τ_{tot} would be equal to τ_{wall} equal to τ_1 and τ_t - the turbulence stress would be 0. That would be equal to μ times du by dy at y equal to 0.

So, integration of this would give me u into τ_{wall} divided by μ times y plus constant, but u is equal to 0 at y equal to 0 and therefore, c is equal to 0; therefore, I get u equal to $\tau_{wall} y$ by μ . If I multiply and divide this by ρ , then you will see, I will get this τ_{wall} divided by ρ will become u_{τ}^2 into y by ν . If I take $1/\nu$ on this side, I will get u over u_{τ} divided by u_{τ} , which is $y u_{\tau}$ by ν . In effect, this is u^+ plus is equal to y^+ plus in the laminar sub layer. In the laminar sub layer, u^+ plus would be simply equal to y^+ plus and that is what I shown here, so u^+ plus is equal to y^+ plus.

(Refer Slide Time: 20:10)

Forms of $F(y^+)$ - 1 - L24($\frac{6}{18}$)

To begin with, we assume that $dp/dx = v_w = 0$. Then, $\tau_{tot} = \tau_w = \text{const}$. Hence,

- In Laminar sub layer $\tau_{tot} = \tau_w = \tau_l = \mu \partial u / \partial y$ or, upon integration, $u = (\tau_w y) / \mu + C$ where $C = 0$ since, $u = 0$ at $y = 0$. Hence, rearrangement gives $u/u_\tau = y u_\tau / \nu$ or, $u^+ = y^+$.
- When dp/dx is moderate, eqn for $\partial \tau_{tot} / \partial y$ shows that 2nd and 3rd derivatives of u w.r.t. y will be nearly zero. Hence, expanding in Taylor's series about $y^+ = 0$, yields:

$$u^+ = y^+ + \frac{y^{+4}}{4!} \frac{\partial^4 u}{\partial y^{+4}} + \dots$$
- This equation shows that for small values of y^+ , equation $u^+ = y^+$ holds; but at some critical distance away from the wall, u^+ must abruptly depart from linearity.

Now, when dp by dx is moderate, the equation for $d \tau_{tot}$ by dy - now of course, v_w is still 0 - shows there would be little bit of y dependence, there will be y dependence plus pressure gradient; that term is 0.

So, τ_{tot} by τ_w would actually be influenced little bit by distance from the wall and therefore, the second and third derivatives of u with respect to y will be nearly 0. Hence, if we expand this u plus y plus relationship in Taylor series, then about y equal to 0 you will get u plus equal to y plus plus y plus 4 by 4 factorial $d^2 u$ by dy plus 4 plus so on and so forth.

Now, this equation shows that for small values of y plus u plus equal to y plus holds, which is the laminar sub layer, but at some critical distance away from the wall, u plus must abruptly depart from linearity. All right, so there is a way useful little deduction that we will carry over to the next transitional layer.

(Refer Slide Time: 21:25)

Forms of $F(y^+)$ - 2 - L24($\frac{7}{18}$)

- ① In the **Transition Layer**, there are no simple arguments because viscous and turbulent stresses are equally important.
- ② There is however similarity between the inertial sub-range of the energy spectrum and the transitional layer.
- ③ If u' is a representative fluctuation then, the viscous lengthscale is $(\nu / u') \ll \delta$ if the $Re_\tau = (u' \delta) / \nu$ is high.
- ④ A layer covering a range of values of y can therefore be imagined in which the turbulence structure is independent of both δ and the viscous lengthscale ν / u' .
- ⑤ Thus, $\partial u / \partial y$ can only depend on (u' / y) . Now, if local value of u' is taken as u , then, $\partial u / \partial y \propto u / y$. Hence

$$u^+ = \frac{1}{\kappa_B} \ln(y^+) + C_B = \frac{\ln(E_\tau y^+)}{\kappa_B} = C_B - \frac{\ln(E_\tau)}{\kappa_B}$$

Expected departure from linearity is indeed observed.

Now, in the transitional layer, there are no simple phenomenal logical arguments that one can give, because both viscous and turbulent stresses are equally important in the transitional layer. There is however a similarity between the inertial sub range of the energy spectrum and the transitional layer. In that if we said, if u' is a representative velocity to fluctuation, then the viscous length scale would be ν / u' , would be much much less than δ , as we already seen; if the turbulent Reynolds number, $u' \delta / \nu$ is high.

A layer covering a range of values of y can therefore be imagined, in which the turbulence structure is independent of both δ - the large scale, as well as the viscous - very very viscous length scale ν / u' . This is how we characterize the inertial sub range, as being relatively uninfluenced by either the very large scale or very very viscous scales.

How should du / dy vary then, in this region? The du / dy can only depend on u' divided by y . If we for a moment say that u' would be proportional to u_τ , then du / dy would be proportional to u_τ / y .

(Refer Slide Time: 23:02)

Handwritten derivation on a piece of paper:

$$\frac{du}{dy} \propto \frac{u}{y}$$

$$\frac{du}{u} = \frac{1}{\kappa \tau} \frac{dy}{y} + C_{tr}$$

$$u = \frac{1}{\kappa \tau} y + C_{tr}$$

$$\frac{du}{dy} = \frac{1}{\kappa \tau} + \frac{C_{tr}}{y}$$

$$u = \frac{1}{\kappa \tau} y + C_{tr}$$

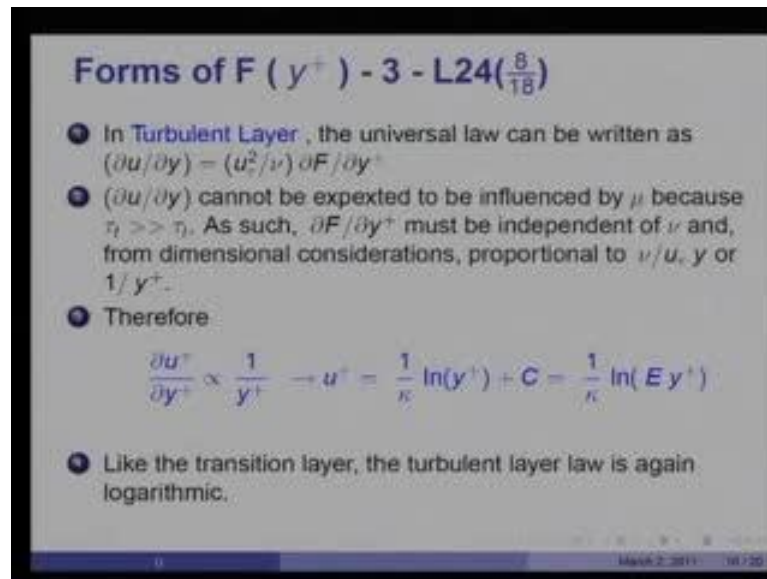

$u = \frac{1}{\kappa \tau} y + C_{tr}$
Transitional layer

If I said that du by dy is proportional to u tau by y , then I will get, let us say du by dy equal to - I am going to now call kappa transition u tau by y and if I were to integrate this, I will get u equal to 1 over kappa transition u tau into \ln of y plus a constant of integration, which is c transition. Before I do that in fact, I can say that if I make this du plus multiplied by u tau and make this dy plus multiplied by - because y plus is equal to u tau y by nu , so dy being changed to - that will become nu by u tau that will equal 1 over kappa transition u tau divided by y nu by u tau. Then, you will see that this u tau gets cancel with this, this gets cancelled with that. I will have essentially du plus by dy plus equal to kappa transition 1 over y plus or I would get, u plus equal to 1 over kappa transition \ln y plus plus a constant of integration C tr.

If this is the law that applies to the transition layer, then it does indeed show that there is a clear departure from u plus equal to y plus, which was in the laminar sub layer; this is now in the transitional layer.

We had anticipated that there would be some distance y plus at which this transition would take place sudden departure in the slope du plus dy plus, which was equal to 1 , now becomes 1 over kappa transition, 1 over y plus. So, there is a sudden change in the velocity gradient and therefore, the velocity itself.

(Refer Slide Time: 25:47)

So, the expected departure from linearity in the u plus y plus law is already attained. Now, indecently this equation can also be recast as ln E transition y plus by K transition, where C transition would be ln E transition by K transition, which is simple.

(Refer Slide Time: 25:55)

Let us turn to the fully turbulent layer. Now, what we are looking for is the u plus equal to F y plus for the turbulent layer. Therefore, this will be 1 over tau du by dy equal to d F by dy plus into dy plus by dy or that would be equal to d F by dy plus into u tau by nu.

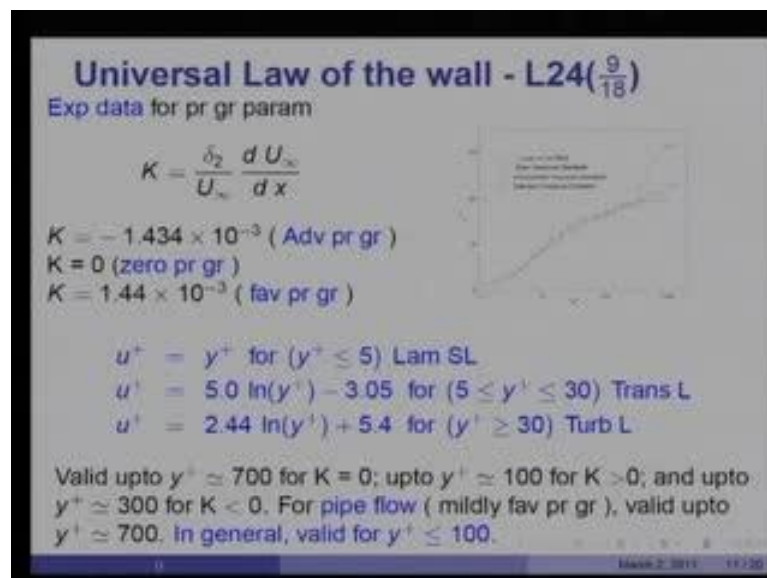

Therefore, you see du by dy in the turbulent layer would be $u \tau^2$ by νdF by dy plus.

Now, of course, in the fully turbulent layer, μ_t is much much greater than μ . So, we do not expect ν to play any significant role in the fully turbulent part of the inner layer. Therefore, this expression must be independent of ν . Therefore, dF by dy plus must be proportional to ν divided by $u \tau y$, so that dimensionally the two sides are correct, or this is nothing but proportional to $1/y$ plus.

Therefore, we get du plus by dy plus as being proportional to $1/y$ plus, this again gives u plus equal to $1/\kappa \ln y$ plus. Now, this will be plus for a constant of integration.

So, the fully turbulent layer also suggests a logarithmic law, but the values of κ and C may be different from those of the transitional layer.

(Refer Slide Time: 28:29)

Now, let us look at the experimental data, because, so far, we have put up phenomenological argument. So, let us look at the experimental data, in which, we look at this parameter, which is the pressure gradient parameter; δ_2 divided by U_∞ dU_∞ by dX .

I am looking at three types of flows; one is the adverse pressure gradient boundary layer, K equal to minus 1.434 into 10 raise to minus 3; K equal to 0 is the 0 pressure gradient boundary layer, because U infinity would be constant; K equal to 1.44 into 10 raise to minus 3, which is the favorable pressure gradient; what does this show? The experimental data are circles, it show 0 pressure gradient boundary layer; squares, show favorable pressure gradient boundary layer; triangles, show adverse pressure boundary layer.

Now, you can see right up to 5, 10, 30 or almost, let us say, up to about a 100, there is a complete collapse of all experimental data on u plus versus y plus - u plus versus y plus. u plus is a linear scale and y plus is a logarithmic scale. up to bar 100 you will see that there is a complete universality irrespective of the pressure gradient. The favorable pressure gradient boundary layer data begin to depart from - let us say somewhere around about 300. The 0 pressure gradient data seem to do quite well, even up to Reynolds number of - I mean y plus of almost 700. But, the adverse pressure gradient data seem to begin to depart at about 300. The favorable pressure gradient data seem to depart say at about 150 or so, from the universality.

So, we can say, up to about 100, the velocity profile in these coordinates u plus versus y plus is almost universal. How does it fit? u plus equal to y plus, it seems is valid up to y plus less than or equal to 5, this is what we identify. This is y plus equal to 5 here, is identified as laminar sub layer. Then, there is a change in slope as you can see and that is the transitional layer up to about 30 that is given by $5 \ln y$ plus minus 3.05. This implies that one over kappa transition is 5; therefore kappa transition must be 0.2. That region extends from y to about 30 that we identify as the transitional layer. u plus equal to $2.44 \ln y$ plus plus 5.4 seems to apply for y plus greater than 30 and that we would say as the turbulent layer.

So, the main observations are for K equal to 0, 0 pressure gradient boundary layer. These laws apply up to y plus equal to 700. I have drawn these laws by the solid line that extend right till about 2000 - y plus up 2000. For favorable pressure gradient y plus of 100 seems to be the upper limit of applicability, whereas again for adverse pressure gradient, it seems to be about 300 y plus of 300. For pipe flow, which is a very mildly favorable pressure gradient, which I have not shown here, in fact then experimental data

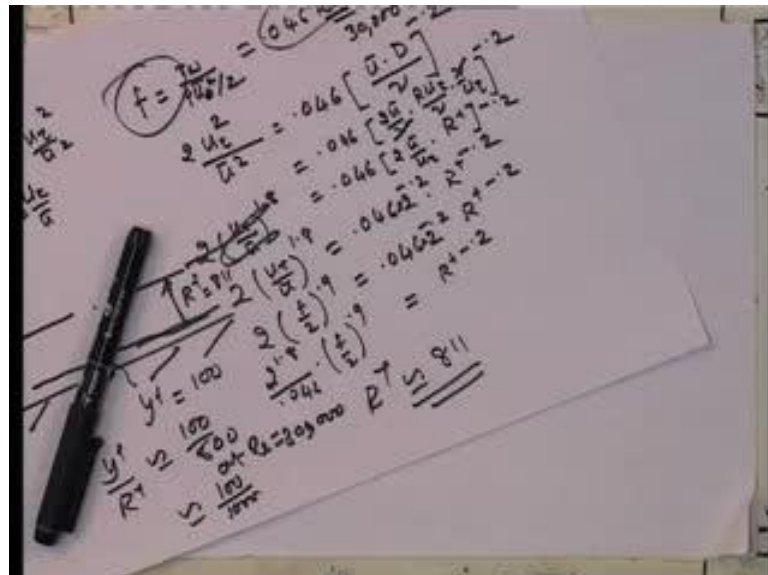

show that again, like K equal to 0 case, experimental data for pipe flow would also fall on the universal laws, till about y^+ plus of 700.

But, it is safe, therefore to say that in general, irrespective of the pressure gradient that we would encounter, the region y^+ plus less than 100 seems to be almost certainly universal - y^+ plus less than 100 seems to be almost certainly universal.

So, we have discovered that the inner layer in the absence of v w , but very moderate pressure gradients does actually have a reasonably universal structure. But, the moment you exceed y^+ plus of 100, the outside pressure gradient effects - that is the other switch we had ignored begin to play their role. Velocity profiles do depart from this universal law that we have identified.

The main changes occur only in the fully turbulent part of the inner layer. The laminar sub layer and the transitional layer are somehow completely insular; they are not affected by the pressure gradient at all. The inner smaller region of the inner layer is also up to about 100, is also universal, but beyond 100, the pressure gradient effect starts playing a constant of integrations role, all right.

(Refer Slide Time: 34:41)

So, what is this special about y^+ plus of 100? Well, it either - I will show shortly, it corresponds to say about 10 to 15 percent of the boundary layer thickness. We can explain this from for a pipe flow.

So, for example, in a pipe flow, f friction factor, which is $\tau_{\text{wall}} / (\rho u_{\text{bar}}^2)$ divided by 2 is $0.46 \text{Re}^{-0.2}$. So, if I take a Reynolds number of let us say 30000; then what am I saying? This relationship actually can be shown $\tau_{\text{wall}} / (\rho u_{\text{bar}}^2) = 0.046 \text{Re}^{-0.2}$ into u_{bar}^2 divided by ν^2 is equal to $0.046 \text{Re}^{-0.2}$ into u_{bar}^2 into diameter divided by ν raise to minus 0.2.

If I were to define here, $0.046 \text{Re}^{-0.2} u_{\text{bar}} / \nu = R_{\text{u}} \tau_{\text{u}} / \nu$ into ν by u_{bar}^2 raise to minus 0.2. Then, you will see this is equal $0.046 \text{Re}^{-0.2}$ into this ν bar gets cancelled with this ν bar, I have $2 \text{ times } u_{\text{bar}} / \nu = R_{\text{u}} \tau_{\text{u}} / \nu$ or you will see therefore, this becomes $2 \text{ times } -$ if I take this term on this side, then you will see, I get $2 \text{ times } u_{\text{bar}} / \nu = R_{\text{u}} \tau_{\text{u}} / \nu$ into u_{bar}^2 raise to 1.8 is equal to $0.046 \text{Re}^{-0.2}$ into $R_{\text{u}} \tau_{\text{u}} / \nu$ raise to minus 0.2. All right, what is u_{bar} / ν ? Well, this is the friction factor, the friction factor is actually equal to $2 \text{ times } u_{\text{bar}} / \nu$ square and therefore, u_{bar} / ν is actually under root of f by 2.

So, in other words, I get here $2 \text{ times } f$ by $2 \text{ raise to } 0.9$ equal to $0.046 \text{Re}^{-0.2}$ into $R_{\text{u}} \tau_{\text{u}} / \nu$ raise to minus 0.2. $R_{\text{u}} \tau_{\text{u}} / \nu$ raise to minus 0.2 would be equal to $2 \text{ raise to } 1.8$ divided by $0.046 \text{Re}^{-0.2}$. Therefore, if I take now Reynolds number of 30000, then I can get the value of f from our usual relationship and therefore, I can show that $R_{\text{u}} \tau_{\text{u}} / \nu$ will be about 811; that is what I have shown here.

So, $R_{\text{u}} \tau_{\text{u}} / \nu$ would be about 811; that is at the axis of the pipe from the wall - $R_{\text{u}} \tau_{\text{u}} / \nu$ would be about 811, whereas in the inner layer where universality exists, y^+ is about 100. So, y^+ by $R_{\text{u}} \tau_{\text{u}} / \nu$ is approximately 100 by 800 at Reynolds number of 30000. If the Reynolds number was bigger, then this could go up to 100 by 1000 even or 1200 or something like that.

So, we are essentially talking about a region of the order of 12 percent, 15 percent region, which defines the inner layer, all right.

(Refer Slide Time: 39:16)

Thickness of Inner Layer - L24($\frac{10}{18}$)

- 1 The general limit of $y^+ \leq 100$ corresponds to $\sim 15\%$ of the width of the shear layer.
- 2 For example, in a pipe flow, $f = 0.046 Re_D^{-0.2} = 2(u_\tau/\bar{u})^2$.
Then for $Re_D = 30,000$ (say),
 $R^+ = R u_\tau/\nu = 0.0758 \times Re_D^{0.9} = 811$.
Therefore, $y_{inner}/R = 100/811 = 0.12$ or 12% .
- 3 The constants in the logarithmic region are:
 $N_B = 0.2$, $C_B = -3.05$ and $E_B = 0.543$ (Transition),
 $\kappa = 0.41$, $C_T = 5.4$ and $E = 9.512$ (Turbulent)
- 4 Rather than a 3-layer universal law, we now seek a **continuous law of the wall** from theory. Recall that the 3-layer law is based on ignorance of the **bursting** phenomenon in the Lam sub layer which, in turn, will influence the heat/mass transfer rates at the wall. Also, effects of dp/dx and v_w were ignored.

The constants, we have identified as I shown here. The constants of kappa transition will be 0.2, kappa for the turbulent layer from 2.44 would be 0.41 and C transition would be 5.4. Of course, likewise, each transition and E of the turbulent layer will be 0.543 and 9.512; this is just another way of writing these two.

The three layer law is very nice, but, as we said, it has very sharp discontinuities. What we would really like, is to have, is continuous law of the wall. How do we do it?

(Refer Slide Time: 40:16)

Prandtl's mixing length-1 - L24($\frac{11}{18}$)

- 1 In analogy with the Stokes's law for laminar shear stress $\tau_t = \mu \partial u/\partial y$, we introduce a model due to Boussinesq, $\tau_t = -\rho \bar{u}' v' = \mu_t (\partial u/\partial y)$.
- 2 Prandtl suggested that

$$\mu_t = \rho l_m \bar{v}' \rightarrow \bar{v}' \simeq l_m \left| \frac{\partial u}{\partial y} \right|$$
$$\tau_t = \rho l_m^2 \left| \frac{\partial u}{\partial y} \right| \frac{\partial u}{\partial y}$$

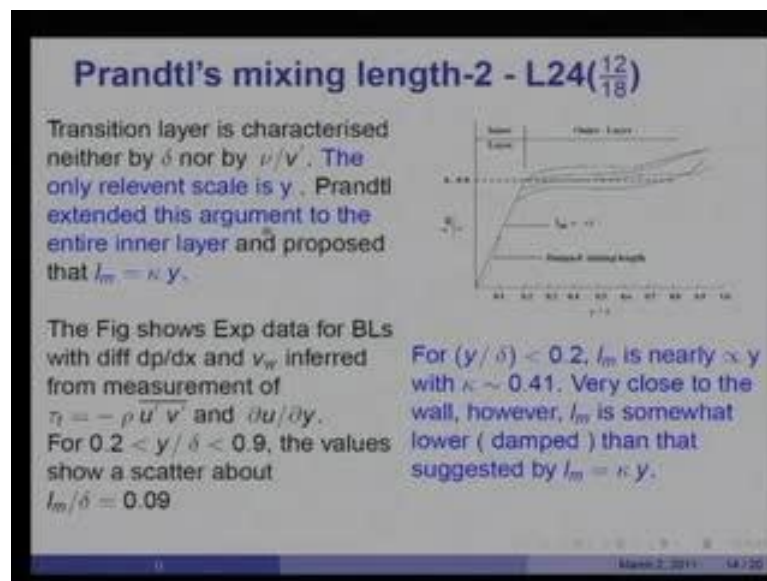

where \bar{v}' is velocity fluctuation responsible for transverse momentum transfer and l_m is mean eddy size in the inner layer. Note that unlike μ , turbulent viscosity μ_t is a property of the flow.

So, we seek now a continuous law of the wall, rather than this three layered description - mathematical description. To do that what I am going to do is, allow for this bursting phenomenon, as well as effects of dp/dx and v_w .

So, in analogy with Stokes law, for laminar shear stress, $\tau = \mu \frac{du}{dy}$. We introduce a model due to Boussinesq, as $\tau = -\rho \overline{u'v'}$ equal to $\mu_t \frac{du}{dy}$. Then, Prandtl suggested, in analogy with how laminar viscosity is defined, in $\rho \times l_m \overline{v' \frac{du}{dy}}$ equal to $\overline{v' \frac{du}{dy}}$ was like $l_m \frac{du}{dy}$. Therefore, τ_t becomes $\rho l_m^2 \frac{d^2u}{dy^2}$, this as issues we considered in our formula aspects as well. Where, $\overline{v'}$ is the fluctuation responsible for transverse momentum transfer and l_m is the mean eddy size in the inner layer- sort of notional mean eddy size.

Note that unlike μ_t turbulent viscosity, μ_t is a property of the flow, whereas μ is actually the property of the fluid. So, that is the difference between μ and μ_t - the turbulent viscosity.

(Refer Slide Time: 41:26)

Now, the second question is how mixing length l_m varies. So, the transitional layer is characterized neither by δ nor by ν/v' , so the only relevant scale is y . Therefore, Prandtl extended this argument to the entire region of the inner layer and proposed that l_m would be κy ; some constant that is directly proportional to y in the inner part of the layer.

Now, the experimental data for the measured, from velocity profiles of 1 m show this. This is y axis, 1 m divided by delta and this is y divided by delta, I am going from 0 to 1. Now, experimental data do show, except for this little damping, 1 m is in fact quite linear till about let us say 0.18 or 0.2, let us say this is what we call the inner layer, but, beyond that point, the 1 m begins to show lots of scatter.

Now, we are considering here flows in adverse pressure gradient, favorable pressure gradient, 0 pressure gradient, as well as pipe flows, many other ducted flows and so on so forth. So, this seems to be quite peculiar about mixing length that it is nearly constant in inner layer. It is nearly linear in the inner layer, say about up to about 20 percent or 15 percent and then it begins to show lots of scatter about a value of 0.09.

Mind you, it is somewhat difficult to accurately measure 1 m in the outer layer, because du/dy in this region is also very small you see and therefore, it becomes difficult to measure this value of 1 m very accurately.

Now, indecently the boundary layers with different pressure gradients, as well as v w, as I said, I have been included for the 0.2 to 0.9 region. The values show a scatter about 1 m by delta equal to 0.09.

(Refer Slide Time: 44:17)

Van-Driest Hypothesis - L24(¹³/₁₈)

- In the region where $l_m = \kappa y$ holds, $\tau_t = \tau_w = \rho(\kappa y)^2 (\partial u / \partial y)^2$ or, taking the sq root, $\partial u^+ / \partial y^+ = 1 / \kappa y^+$. This integrates to $u^+ = \ln(E y^+) / \kappa$ for the turbulent inner layer.
- To include effects of fluctuations on the transition and laminar sub layer, Van-Driest proposed

$$l_m = \kappa y \left[1 - \exp\left(-\frac{y^+}{A^+}\right) \right]$$

$$\text{or } \mu_t = \rho(\kappa y)^2 \left[1 - \exp\left(-\frac{y^+}{A^+}\right) \right]^2 \frac{\partial u}{\partial y}$$

where for a smooth wall, $A^+ \approx 26$. Note that μ_t is zero only at the wall and in regions where viscosity is influential ($y^+ < 30$), l_m is smaller than Prandtl's mixing length. The amplitude of fluctuations decrease exponentially as $y \rightarrow 0$.

But, for y over delta less than 0.2, 1 m is nearly proportional to kappa - 0.41. Very close to the wall, 1 m is somewhat lower damped and then suggested by 1 m equal to kappa y.

Van Driest suggested that this damping actually occurs due to the effects of fluctuations in the transitional layer and therefore, he said the l_m of Prandtl should be modified by introducing a damping function $1 - \exp(-y^+ / A^+)$. Therefore, from the previous slide, μ_t would therefore be equal to $\rho u^+ \kappa y^+ \left(1 - \exp(-y^+ / A^+)\right)^2$.

Whereas, from experimental data, it is found that $A^+ = 26$ for a smooth wall, will bring about the amount of damping required in line with what is observed in experiments. μ_t of is 0 at the wall, because y is equal to 0 there and in regions where viscosity is influential that is $y^+ < 30$, l_m is smaller than the Prandtl's mixing length.

The amplitude of fluctuations decreases, thus exponentially as y tends to 0; that is what we expect, when viscosity begins to play its role in dissipation.

(Refer Slide Time: 45:52)

Continuous Law - L24(14/18)

- To produce a continuous law of the wall, recall that

$$\frac{\tau_{tot}}{\tau_w} = 1 + \rho^+ y^+ + v_w^+ u^+$$

$$= \left[1 + \left[\kappa y^+ \left\{ 1 - \exp\left(-\frac{y^+}{A^+}\right) \right\} \right]^2 \frac{\partial u^+}{\partial y^+} \right] \frac{\partial u^+}{\partial y^+}$$
- However, if the stress-ratio is assumed to be unity then, the effects of ρ^+ and v_w^+ can be absorbed in a suitably defined A^+ .
- Thus, with $\tau_{tot}/\tau_w = 1$, we obtain

$$\frac{\partial u^+}{\partial y^+} = \frac{-1 + \sqrt{1 + 4a}}{2a} \quad a = \left[\kappa y^+ \left\{ 1 - \exp\left(-\frac{y^+}{A^+}\right) \right\} \right]^2$$

$$u^+ = \int_0^{y^+} \frac{\partial u^+}{\partial y^+} dy^+ \quad (\text{Continuous Law})$$

Numerical integration is required.

So, in order to develop continuous law of the wall - τ_{tot} by τ_w , which was shown earlier to be $1 + \rho^+ y^+ + v_w^+ u^+$. Now, it can appear in this fashion, where this μ_t expression has been used to define τ_{tot} divided by τ_w and this is a long expression.

However, if the stress ratio is assumed to be unity, then effects of ρ^+ and v_w^+ can be absorbed in a suitably defined A^+ .

So, what we are saying is we are going to cheat on this equation. We will say, let p^+ equal to 0 and v_w^+ equal to 0, so that τ_{tot}^+ / τ_w^+ will be exactly equal to 1 and would be equal to that relationship. But, to account for effect of p^+ and v_w^+ we would simply tune the value of A^+ , here that is the damping constant.

If you take τ_{tot}^+ / τ_w^+ equal to 1, we obtain du^+ / dy^+ as a quadratic in du^+ / dy^+ . The solution is simply $u^+ = \int_0^{y^+} du^+ / dy^+ dy^+$. The a here is given by that damping function.

(Refer Slide Time: 47:09)

Predictions - L24(15/18)

Exptl data for different BLs with different dp/dx and v_w are matched with predictions tuning A^+ in each case. Kays and Crawford propose

$$A^+ = \frac{25}{a \left[v_w^+ + b \left\{ \frac{p^+}{1 + c v_w^+} \right\} \right] + 1}$$

with $a = 7.1$, $b = 4.25$, $c = 10$
 and if $p^+ > 0$, $b = 2.9$, $c = 0$
 or, if $v_w^+ < 0$, $a = 9$

Predictions agree very well
 upto $y^+ = 500$ for Zero pr. gr.,
 upto $y^+ \approx 100$ for Fav pr. gr.
 and
 upto $y^+ \approx 200$ for Adv. pr. gr.

So, you need numerical integration to predict u^+ as a function of y^+ and that is what I have done here. Experimental data from different boundary layers with different dp/dx and v_w are matched with predictions by tuning A^+ in each case. Kays and Crawford have proposed A^+ to be 25 divided by a into v_w^+ plus b into all this function plus 1. We will make use of this a^+ later on in actual computations of friction factors Nusselt number.

But, presently just see this; we do manage to predict the continuous law of the wall. Quite well predict the experimental data in favorable pressure gradient, adverse pressure gradient, as well as $a = 0$ pressure gradient boundary layers; up to 500 or 700 in 0 pressure gradient, up to 100 in favorable pressure gradient and up to - about 200 or 250 in adverse pressure gradient.

Therefore, we can say that we have now found a method for calculating universality of the inner layer in a continuous manner.

(Refer Slide Time: 48:46)

Outer Layers-1 - L24(16/18)

- **Outer layers** can hardly be expected to be universal because the large eddy structure there is severely influenced by dp/dx and other body forces. We need **turbulence models** for this region.
- **Short-cut** methods have been developed. For example, for zero pr. gr. BL, vel profiles at different axial locations can be unified by

$$\frac{u_\infty - u}{u_\tau} = F\left(\frac{y}{\delta}\right) = 1 - \cos\left(\pi \frac{y}{\delta}\right) \text{ (wake function)}$$

$$u^+ = \frac{1}{\kappa} \ln(y^+) + C + \frac{A}{\kappa} \left\{ 1 - \cos\left(\pi \frac{y}{\delta}\right) \right\}$$

where, $A \approx 0.55$, $\kappa = 0.4$ and $C = 5.1$.

This is very useful when we do friction factor and number. Now, of course, the outer layers do not have any universality, they are big, they are significantly influenced by the pressure gradient and other effects. But, nonetheless efforts have been made - short cut methods have been made to universalized outer layers in this fan.

These are called the velocity defect law. $u_\infty - u$ over u_τ equal to $1 - \cos \pi y / \delta$. Therefore, the total velocity function is given by this A equal to 0.55 κ equal to 0.4 and C equal to 0.51.

(Refer Slide Time: 49:18)

Outer Layers-2 - L24(17/18)

- There are limitations. For example, from expt data for ducted flows, $A \simeq 0$. Similarly, for finite dp/dx , $A = F(x)$.
- Also, although u^+ profile is unified, measured v/u_* and τ_w cannot be. Thus, **conditions for similarity** cannot be established for turbulent BLs as was possible with laminar BLs.
- However, **only u-profile similarity** can be established from computer curve-fitting of exptl data.

$$\frac{u_* - u}{u_*} = F\left(\frac{y}{\delta_3}\right) \rightarrow \delta_3(x) = - \int_0^\infty F dy$$
$$G(x) = \int_0^\infty F^2 d\left(\frac{y}{\delta_3}\right)$$

- For $U_* = C x^m$ BLs and $m < 0$,
 $G \simeq 6.2 (\beta + B + 1.43)^{0.482}$ for $(-1 < \beta + B < 12)$ where,
 $\beta = (\delta_1/\tau_w) dp/dx$ and $B = \rho \nu_w u_* / \tau_w$.

This of course applies only to 0 pressure gradient boundary layer, but not in general. There are other methods for outer layers, but I will not go into that at the moment.

(Refer Slide Time: 49:30)

Summary - L24(18/18)

- We have shown that although the **Inner Layer** universality can be established for a wide variety of turbulent flows, **Outer layer** similarity is difficult to establish.
- For complete description of outer layers, we need to solve the RANS equations via **turbulence models**. The inner layer universality can be exploited in two ways
 - To derive approximate correlations for f and Nu
 - To specify wall-boundary conditions at $y^+ \simeq A^+$ when outer layers are computed by RANS equations. This achieves computational economy.
- To prepare the ground for studying turbulence models, in the next lecture, we shall explore the likely **interaction between Inner and Outer Layers**.

So, in summary, I would say that we have shown that although the inner layer universality can be established for a wide variety of turbulent flows, outer layer similarity is difficult to establish.

For complete description of the outer layers, we need to solve the RANS equations using turbulence models. The inner layer universality can be exploited in two ways. That is to derive approximate correlations for friction factor and Nusselt number, to specify wall boundary conditions at $y^+ = A^+$ when outer layers are computed by RANS equations. This achieves computational economy, but this is an aspect that the CFD analysis essentially worries about.

Now, to prepare the ground for studying turbulence models, in the next lecture, we shall explore the likely interaction between inner and outer layers; thank you.
