Lecture 2

Module 3 Finite Difference Method

Finite Difference by General Approximation and Polynomials

Hello everyone, so in last lecture of this module, we learned how to discretize the first derivative and second derivative using finite difference method and for that we use Taylor series expansion. Now today will have been lecture two, Finite Difference by General Approximation and Polynomials. So, here we will use some other methods to find the finite difference approximation of the derivatives. So, let us first use the general approximation.

(Refer Slide Time: 01:13)

General approximation to find finite difference approximation in uniform grid

$$\frac{\partial^2 f}{\partial x^2} \rightarrow f_i, f_{i+1}, f_{i-1}$$

$$\frac{\partial^2 f}{\partial x^2} = \alpha f_i + \beta f_{i+1} + \gamma f_{i-1}$$

$$\frac{\partial^2 f}{\partial x^2} = \alpha f_i + \beta \left(f_i + \Delta x \frac{\partial f}{\partial x} + \frac{(\Delta x)^2}{2!} \frac{\partial^2 f}{\partial x^2} + \frac{(\Delta x)^3}{3!} \frac{\partial^3 f}{\partial x^3} + \dots \right) + \gamma \left(f_i - \Delta x \frac{\partial f}{\partial x} + \frac{(\Delta x)^2}{2!} \frac{\partial^2 f}{\partial x^2} - \frac{(\Delta x)^3}{3!} \frac{\partial^3 f}{\partial x^3} + \dots \right)$$

$$\frac{\partial^2 f}{\partial x^2} = (\alpha + \beta + \gamma) f_i + (\beta - \gamma) \Delta x \frac{\partial f}{\partial x} + (\beta + \gamma) \frac{(\Delta x)^2}{2} \frac{\partial^2 f}{\partial x^2} + \frac{(\beta - \gamma) (\Delta x)^3}{6} \frac{\partial^3 f}{\partial x^3} + \dots$$

$$f_i \rightarrow \alpha + \beta + \gamma = 0 \rightarrow \alpha = -(\beta + \gamma) = -2/\beta$$

$$\frac{\partial f}{\partial x} \rightarrow (\beta - \gamma) \Delta x = 0 \Rightarrow \beta = \gamma \rightarrow \alpha = -\frac{2}{(\Delta x)^2}$$

$$\frac{\partial^2 f}{\partial x^2} \rightarrow (\beta + \gamma) \frac{(\Delta x)^2}{2} = 1 \Rightarrow \beta + \gamma = \frac{2}{(\Delta x)^2}$$

$$\beta = \gamma = \frac{1}{(\Delta x)^2}$$

$$\frac{\partial^2 f}{\partial x^2} = -\frac{2}{(\Delta x)^2} f_i + \frac{1}{(\Delta x)^2} f_{i+1} + \frac{1}{(\Delta x)^2} f_{i-1}$$

$$= \frac{f_{i+1} - 2f_i + f_{i-1}}{(\Delta x)^2} + O((\Delta x)^2)$$

So, General approximation to find finite difference approximation using or in uniform grid. So, in last class also we have used the uniform grid in that sense the spacing, grid spacing is same delta x is same, so here also we will considered, let us say this is your grid and these are the points i i is the index these are the discrete points in X direction and this your i minus 1.

So, in general approximation what is the advantage if you want to find some approximation of derivatives first derivative or second derivative using some discrete points, so that you can do easily. Let us say that we want to find the derivative del 2 f by del x square, using three points f i f i plus 1 and f i minus 1. So, the values at i point is f i i plus 1 point f i plus 1 and f i minus 1. So, we want to find this finite difference approximation of del 2 f by del x square using the values of f i f i plus 1 and f i minus 1.

In last class what we did we use some algebra and did some subtraction or addition and we found the finite difference approximation. Now, in general approximation, we are telling that we want to find the finite difference approximation of any derivative using some discrete values at $i+1$ and $i-1$ in this case.

So, what we will do for this, first we will write $\frac{\Delta^2 f}{\Delta x^2}$ is equal to some coefficient α will get, plus β , f_{i+1} plus γ f_{i-1} . So, this is the finite difference approximation now we need to find the values of α , β and γ . So, to do that, what we will do, we will expand this f_{i+1} and f_{i-1} using Taylor series expansion and the coefficients in the right hand side will equate with the coefficient in the left hand side.

So, first let us expand it, so, we can write $\frac{\Delta^2 f}{\Delta x^2}$ is equal to αf_i last β . Now we will expand it using Taylor series expansion, so that you can write $f_{i+\Delta x}$ or the distance between these discrete points is Δx , and this also Δx because it is uniform grid.

We have the value here f_i here f_{i+1} and f_{i-1} . So, now we will write $\Delta x \frac{df}{dx}$ by Δx plus $\frac{\Delta x^2}{2}$ by $\frac{d^2 f}{dx^2}$ plus $\frac{\Delta x^3}{6}$ by $\frac{d^3 f}{dx^3}$ and other higher order terms. Similarly, let us expand this f_{i-1} . So, plus γ $f_{i-\Delta x}$ plus $\frac{\Delta x^2}{2}$ by $\frac{d^2 f}{dx^2}$ minus $\frac{\Delta x^3}{6}$ by $\frac{d^3 f}{dx^3}$ plus higher other terms.

So, now we can now simplify it $\frac{\Delta^2 f}{\Delta x^2}$, so all the f_i coefficient you write together, so you can write α plus β plus γ . So, this is your f_i coefficient similarly, $\frac{df}{dx}$ whatever coefficient you have that you write, so $\frac{df}{dx}$ you have β minus γ $\Delta x \frac{df}{dx}$.

Now you write for $\frac{\Delta^2 f}{\Delta x^2}$. So, now if you find this you will get, so β , so it will be β plus γ because it is plus so it will $\frac{\Delta x^2}{2}$, factorial 2 is 2, $\frac{\Delta^2 f}{\Delta x^2}$. After that you will have plus, so you have a β minus γ β minus γ . So, you have $\frac{\Delta x^3}{6}$ factorial 3 $\frac{\Delta^3 f}{\Delta x^3}$ and other terms.

So, you can see that now you compare the coefficients. So, f_i coefficient in the right hand side is α plus β plus γ in left hand side there is no term associated with f_i so,

alpha plus beta plus gamma will be 0. So, you can write, so for f_i I am just writing the coefficients if you compare so, it will be alpha plus beta plus gamma will be 0.

Similarly compared the coefficients of the $\frac{df}{dx}$. So, in the left hand side no term is there associated with $\frac{df}{dx}$. So, it will be 0, so $\frac{df}{dx}$ if you compare the coefficients, so it will be beta minus gamma into Δx will be 0 and if you compare $\frac{d^2f}{dx^2}$ by Δx^2 . So you will get beta plus gamma Δx^2 by 2 will be now, you see, we have left hand side $\frac{d^2f}{dx^2}$ whose coefficient is 1. So, you can write this equal to 1.

So, to find the three unknown alpha, beta, gamma from these three equations will be able to find. So, from the second one you can write, beta is equal to gamma. So if beta is equal to gamma from here you can write, you can write, so it will be beta plus gamma is equal to $2 \Delta x^2$.

So, that means you will get beta is equal to gamma. So, beta will be gamma is equal to $\frac{1}{2} \Delta x^2$, because it is 2β . So, 2β will cancel out. So, now, from this you can now write alpha plus beta plus gamma is equal to 0. So, from here you can write alpha is equal to minus beta plus gamma, which is nothing but minus Δx^2 .

So, you can write alpha is equal to. So, minus Δx^2 whole square. So, we found the coefficients alpha beta gamma just comparing left hand side to right hand side the coefficients of f_i $\frac{df}{dx}$ and $\frac{d^2f}{dx^2}$. So, now you know alpha beta gamma So, you can write the approximation of $\frac{d^2f}{dx^2}$ as $\frac{d^2f}{dx^2}$ is equal to. So, alpha is minus Δx^2 f_i then beta. So, beta is your plus $\frac{1}{2} \Delta x^2$, this your f_i plus 1 and gamma is also same $\frac{1}{2} \Delta x^2$ f_i minus 1.

So, if you rearrange it, so you will get Δx^2 f_i plus 1 minus twice f_i plus f_i minus 1. So, you know that already we have derived it. So, it is a central difference approximation of the second derivative $\frac{d^2f}{dx^2}$ and we are getting the same finite difference approximation. Now, what will be the order of accuracy, so you can see order of accuracy is beta is equal to gamma so beta equal to gamma.

So, if you see in this term, so beta is equal to gamma. So, this term will become 0. So, this term will become 0. So, then another term will be there associated with these. So, if you write it, so it will be beta plus gamma Δx^4 by factorial 4 $\frac{d^4f}{dx^4}$. So, if you see it, so, it will be beta plus gamma.

So, another show here if you add another term here and this if you add it you will get this. So, now, beta plus gamma. So, these you have delta x to the power 4 and beta and gamma contents divided by delta x square. So, that means, that will be divided so your, you are you can see that beta and gamma contents 1 by delta x square. So, if you divide it beta plus gamma. So, here, so this term will be, so this whole term will be order of delta x whole square because beta and gamma is 1 by delta x square you can see here.

So, delta x to the power 4 divided by delta x square so it will be order of delta x square. So, it is order of accuracy of will be delta x square. So, because this time is becoming 0, because beta minus gamma is 0 already we have seen, so, this term will become 0. So, the other term will contribute. So, it is the leading term in that truncation error. So it will be order of delta x square. So, similarly, let us find the approximation of del f by del x using three points f i f i plus 1 and f i plus 2. So, it is one sided forward difference approximation of del f by del x.

(Refer Slide Time: 12:47)

$$\frac{\partial f}{\partial x} \rightarrow f_i, f_{i+1}, f_{i+2}$$

$$\frac{\partial f}{\partial x} = \alpha f_i + \beta f_{i+1} + \gamma f_{i+2} \approx$$

$$\rightarrow \frac{\partial f}{\partial x} = \alpha f_i + \beta \left(f_i + \Delta x \frac{\partial f}{\partial x} + \frac{(\Delta x)^2}{2!} \frac{\partial^2 f}{\partial x^2} + \frac{(\Delta x)^3}{3!} \frac{\partial^3 f}{\partial x^3} + \dots \right)$$

$$+ \gamma \left(f_i + 2\Delta x \frac{\partial f}{\partial x} + \frac{(2\Delta x)^2}{2!} \frac{\partial^2 f}{\partial x^2} + \frac{(2\Delta x)^3}{3!} \frac{\partial^3 f}{\partial x^3} + \dots \right)$$

$$\rightarrow \frac{\partial f}{\partial x} = (\alpha + \beta + \gamma) f_i + (\beta + 2\gamma) \Delta x \frac{\partial f}{\partial x} + (\beta + 4\gamma) \frac{(\Delta x)^2}{2!} \frac{\partial^2 f}{\partial x^2} + (\beta + 8\gamma) \frac{(\Delta x)^3}{3!} \frac{\partial^3 f}{\partial x^3} + \dots$$

$$f_i \rightarrow \alpha + \beta + \gamma = 0$$

$$\frac{\partial f}{\partial x} \rightarrow (\beta + 2\gamma) \Delta x = 1 \Rightarrow \beta + 2\gamma = \frac{1}{\Delta x}$$

$$\frac{\partial^2 f}{\partial x^2} \rightarrow (\beta + 4\gamma) \frac{(\Delta x)^2}{2!} = 0 \Rightarrow \beta + 4\gamma = 0$$

$$\Rightarrow \beta = -4\gamma$$

$$-4\gamma + 2\gamma = \frac{1}{\Delta x} \Rightarrow -2\gamma = \frac{1}{\Delta x} \Rightarrow \gamma = -\frac{1}{2\Delta x}$$

$$\therefore \beta = -4\gamma = \frac{2}{\Delta x}$$

$$\alpha + \beta + \gamma = 0 \Rightarrow \alpha = -(\beta + \gamma) = -\left(\frac{2}{\Delta x} - \frac{1}{2\Delta x}\right) = -\frac{3}{2\Delta x}$$

$$\frac{\partial f}{\partial x} = -\frac{3}{2\Delta x} f_i + \frac{2}{\Delta x} f_{i+1} - \frac{1}{2\Delta x} f_{i+2}$$

$$= \frac{-3f_i + 4f_{i+1} - f_{i+2}}{2\Delta x} + O[(\Delta x)^2]$$

So, we want to find the finite difference approximation of del f by del x, using three points discrete values at three points f i f i plus 1 and f i plus 2. So, similarly now we will take the discrete points. So, let us take three discrete points i i plus 1 and i plus 2 and separate by separated by uniform distance so this is your delta x and this is also delta x.

So, the value associated with i point is f i, this is your f i plus 1 and this is your f i plus 2. Now, you want to find the first derivative del f by del x using the values f i f i plus 1 and f i plus 2. So, let us write similar way del f by del x. So, we are using the general approximation, so, it will be alpha f i plus beta f i plus 1 plus gamma f i plus 2.

So, similarly we will use the Taylor series expansion for $f(x+1)$ and $f(x+2)$, then we will compare the coefficients with the left hand side and right hand side. So, you can write $f(x)$ by Δx is equal to $\alpha f(x) + \beta \Delta x$, now you write the $f(x+1)$ as $f(x) + \Delta x \frac{df}{dx} + \frac{\Delta x^2}{2} \frac{d^2f}{dx^2} + \frac{\Delta x^3}{6} \frac{d^3f}{dx^3} + \dots$ and other higher order terms and γ now you write for $f(x+2)$.

So, $f(x+2)$ means $f(x)$ means $x + 2\Delta x$. So, it will be $f(x) + 2\Delta x \frac{df}{dx} + \frac{(2\Delta x)^2}{2} \frac{d^2f}{dx^2} + \frac{(2\Delta x)^3}{6} \frac{d^3f}{dx^3} + \dots$ and other higher order terms. So, now, you rearrange it so, $\frac{df}{dx}$ by Δx first you write all the coefficients for $f(x)$, so, together we are writing $\alpha + \beta + \gamma$ because this is your α this is your β and this is your γ .

So, this is into $f(x)$. Now write the coefficients for $\frac{df}{dx}$ by Δx So, this is your $\frac{df}{dx}$ by Δx So, you can write $\beta + 2\gamma$, this is 2 and this is your γ into $\Delta x \frac{df}{dx}$ then you write this term, so it will be plus.

So it will be $\beta + 4\gamma$ into Δx^2 by $\frac{d^2f}{dx^2}$ and the other term will be, say it will be $\beta + 8\gamma$ into Δx^3 by $\frac{d^3f}{dx^3}$ and other higher order terms. Now, you compare the coefficients, so first you compare the coefficients of $f(x)$.

So, in left hand side it is coefficients of $f(x)$ is 0 . So, you can write $\alpha + \beta + \gamma$ is equal to 0 . Similarly $\frac{df}{dx}$ coefficient, left hand side you have 1 and right hand side you have $\beta + 2\gamma$ into Δx is equal to 1 . Similarly you write, $\frac{d^2f}{dx^2}$ coefficient.

So, you can see here $\beta + 4\gamma$ into Δx^2 by $\frac{d^2f}{dx^2}$ is equal to 0 . So, $\frac{d^2f}{dx^2}$ means it is 2 only. So, now you find so you can write from here $\beta + 2\gamma$ is 1 by Δx and from here you can write $\beta + 4\gamma$ is equal to 0 . So, from here you can write β is equal to -4γ . So, from here now, if you put this value here, so you will get β value if you put then you will get $-4\gamma + 2\gamma$ is equal to 1 by Δx .

So, that means you will get -2γ is equal to 1 by Δx . So, you will get γ is equal to $-\frac{1}{2\Delta x}$. So, γ you found, so now β is equal to -4γ . So, β will be -4γ so, it will be 2 by Δx $-\frac{1}{2\Delta x}$ it will be $-\frac{2}{\Delta x}$.

Now, you have $\alpha + \beta + \gamma = 0$. So, you put the values, so α will be $-\beta + \gamma$, so that means $\beta = \frac{2}{\Delta x}$ and $\gamma = -\frac{1}{2\Delta x}$. So, what you will get? So, you will get $-\frac{2}{\Delta x}$ it will be 4 so it will be 3.

So, $4 - 1$ it will be 3. So, now α , β and γ value you have found now you put the values in this expression, in this expression So, what you will get, so $\frac{df}{dx}$. So, what is the value of α α is $-\frac{3}{2\Delta x}$ into f_i , then you will get β , β is $\frac{2}{\Delta x}$, f_{i+1} then f_{i+2} is coefficient is γ . So, γ is $-\frac{1}{2\Delta x}$ f_{i+2} .

So, if you rearrange it, so, you will you are going to get, so $2\Delta x$, so it will be $-\frac{3}{2}f_i$. So, you will get, so 2 so it will be $4f_{i+1}$ and you will get $-\frac{1}{2}f_{i+2}$. So, in last class already we derived this directly from the Taylor series expansion and we got the same expression.

So, this is forward difference approximation of $\frac{df}{dx}$ using three discrete points values. So, f_i , f_{i+1} and f_{i+2} and what will be the order of accuracy of this scheme. So, you can see the first term in the truncation error is this term but this term you can see that $\beta + 4\gamma = 0$. So, this term is going to be zero, so, now next term is $\frac{8}{6}\gamma$.

So, this is the now leading term, so if it is the leading term in the truncation error. So, $\frac{8}{6}\gamma$ will be ordered up on by Δx and here Δx^3 is there so, together these will actually give Δx^3 by Δx . So, it will be Δx^2 . So, the accuracy of this finite difference approximation will be order of Δx^2 .

So, already we have derived it in last class using Taylor series expansion and we could find that the order of accuracy is Δx^2 . So, now we found the derivative using known discrete points we wanted to express the derivative using general approximation. Now let us see how we can discretize using polynomial.

(Refer Slide Time: 22:17)

Finite difference approximation by polynomial

Second order polynomial
 $f(x) = Ax^2 + Bx + C$

$f_i = Ax_i^2 + Bx_i + C \Rightarrow C = f_i$
 $= 0 + 0 + C$

$f_{i+1} = A(x_i + \Delta x)^2 + B(x_i + \Delta x) + C$
 $= A(\Delta x)^2 + B(\Delta x) + f_i \Rightarrow A(\Delta x)^2 + B(\Delta x) = f_{i+1} - f_i \dots (a) \times 2$

$f_{i+2} = A(x_i + 2\Delta x)^2 + B(x_i + 2\Delta x) + C$
 $= A(2\Delta x)^2 + B(2\Delta x) + f_i \Rightarrow 4A(\Delta x)^2 + 2B(\Delta x) = f_{i+2} - f_i \dots (b)$

$(b) - 2 \times (a)$
 $4A(\Delta x)^2 + 2B(\Delta x) - 2[A(\Delta x)^2 + B(\Delta x)] = f_{i+2} - f_i - 2f_{i+1} + 2f_i$
 $2A(\Delta x)^2 = f_{i+2} - f_i - 2f_{i+1} + 2f_i = f_{i+2} - 2f_{i+1} + f_i$
 $\Rightarrow A = \frac{f_{i+2} - 2f_{i+1} + f_i}{2(\Delta x)^2}$

$\Delta x B = f_{i+1} - f_i - \frac{f_{i+2} - 2f_{i+1} + f_i}{2} = \frac{2f_{i+1} - 2f_i - f_{i+2} + 2f_{i+1} - f_i}{2}$
 $\Rightarrow B = \frac{-3f_i + 4f_{i+1} - f_{i+2}}{2\Delta x}$

So, we will now learn finite difference approximation by polynomial, so in this case, we will use the value of this function as polynomial, then its derivative will find and using some given data will be able to find the constants of the polynomial. So first, what do we want to find? We will let us consider a second order polynomial, so first you find second order polynomial.

So, we will write $f(x)$ as $Ax^2 + Bx + C$, so it is second order polynomial now A , B , C are constant, so if you know the $f(x)$ in terms of A , B , C so all these coefficients if unknown then anyway you can easily find the first derivative approximation as well as the second derivative of f this approximation.

Now to find the constant A , B , C we will use some data of these dependent variables. So, for that, let us say that the polynomial, so that using three points. So, this is let us say x and this is your $f(x)$ and your polynomial varies like and we are using uniform spacing. So, in this case, let us say your, this is your, so this is your x_i , and this is your $x_i + 1$ and this is your $x_i + 2$, and we will assume that x_i is equal to 0 because we are starting from here and the spacing is Δx .

So, $x_i + 1$ will be Δx and $x_i + 2$ will be $2\Delta x$ and these are the values of $f_i + 1$, $f_i + 2$ and this is f_i . So, now we have assumed the second order polynomial. So, we can now write f_i as $Ax_i^2 + Bx_i + C$. Similarly, we can write $f_i + 1$ is equal to $A(x_i + 1)^2 + B(x_i + 1) + C$ and $f_i + 2$ we can write $A(x_i + 2)^2 + B(x_i + 2) + C$ because as $f(x)$ we have assumed like the second order polynomial.

So, we can write for $f(x) = x^2 + 1x + 2$ like this. Now, as we have assumed that x is equal to zero and $x + 1$ is equal then Δx and $x + 2$ is $2\Delta x$ because we have uniform spacing. So, we can write these as, so x as 0, so it is $0 + 0 + c$. So, from here you can write the value of C as $f(x)$.

So now similarly now you put $x + 1$ as Δx because here you can see, so you can write A , so this is your $\Delta x^2 + B\Delta x + C = f(x)$. So, from here, so you can write $A\Delta x^2 + B\Delta x = f(x + 1) - f(x)$ and this now you can write $f(x + 2) - f(x + 1) = 2\Delta x$.

So, you can write $A(2\Delta x)^2 + B(2\Delta x) + C = f(x)$, so $f(x)$ you can write. So, from here you can write A so, it will be $4\Delta x^2 + 2B\Delta x = f(x + 2) - f(x)$. So, now you have these two equations and two unknowns A and B C already we have found, so you find the values of A and B . So, this equation you multiply with 2 and subtract with this.

So, equation let us say this is your A and this is your B , so you subtract multiplying this equation A with 2 with the equation B . So, you can write $B - 2A$ into A , so what you will get, so you can see. So this you will you are going to get $2A\Delta x^2 + 2B\Delta x = 2f(x + 1) - 2f(x)$, okay? And you have B , $B = 4A\Delta x^2 + 2B\Delta x = f(x + 2) - f(x)$, so if you subtract it.

So, these term term will get canceled, so you will get $2A\Delta x^2 = f(x + 2) - 2f(x + 1) + f(x)$ here we are writing. So, $f(x + 2) - 2f(x + 1) + f(x)$ you can write this as $f(x + 2) - 2f(x + 1) + f(x)$. So, from here you can write the value of A as $f(x + 2) - 2f(x + 1) + f(x)$ divided by $2\Delta x^2$.

So, let us find the value of B , so B will get. So, from here you can find. So, you will get $f(x + 1) - f(x)$. So, $B = f(x + 1) - f(x) - 2A\Delta x^2$ So, A is this so it will be $f(x + 2) - 2f(x + 1) + f(x)$ divided by $2\Delta x^2$ and so $B = f(x + 1) - f(x) - 2A\Delta x^2$ let us say so $B = f(x + 1) - f(x) - 2A\Delta x^2$.

So, Δx^2 and Δx^2 will cancel out. So, $f(x + 2) - 2f(x + 1) + f(x)$ So, you will get $2f(x + 1) - 2f(x) - 2A\Delta x^2 + 2f(x + 1) - 2f(x) + f(x)$. So, if you divide by Δx , so you will get B as so now divided with Δx or $2\Delta x$ and if you write all these terms. So, $f(x + 1) - f(x)$ you take C , so $3f(x) - 3f(x)$, then you have $f(x + 1) - f(x) + 1$ and so $4f(x) + 1$, so $4f(x) + 1$ and $f(x)^2$ so $f(x) - 2$.

Now, we could find the values of A, B and C. So now if you put here a f x then in this expression, so you will get the f x so what will be the fx.

(Refer Slide Time: 31:27)

$$\begin{aligned}
 A &= \frac{f_{i+2} - 2f_{i+1} + f_i}{2(\Delta x)^2} \\
 B &= \frac{-3f_i + 4f_{i+1} - f_{i+2}}{2\Delta x} \\
 C &= f_i \\
 f(x) &= Ax^2 + Bx + C \\
 \frac{\partial f}{\partial x} \Big|_i &= 2Ax + B = B = \frac{-3f_i + 4f_{i+1} - f_{i+2}}{2\Delta x} \\
 \frac{\partial^2 f}{\partial x^2} \Big|_i &= 2A = \frac{f_{i+2} - 2f_{i+1} + f_i}{(\Delta x)^2}
 \end{aligned}$$

Finite difference approximation by polynomial

Second order polynomial

$$f(x) = Ax^2 + Bx + C$$

$$f_i = Ax_i^2 + Bx_i + C \Rightarrow C = f_i$$

$$f_{i+1} = Ax_{i+1}^2 + Bx_{i+1} + C = A(\Delta x)^2 + B(\Delta x) + f_i \Rightarrow A(\Delta x)^2 + B(\Delta x) = f_{i+1} - f_i = (\Delta x) \times 2$$

$$f_{i+2} = Ax_{i+2}^2 + Bx_{i+2} + C = A(2\Delta x)^2 + B(2\Delta x) + f_i \Rightarrow 4A(\Delta x)^2 + 2B(\Delta x) = f_{i+2} - f_i = (b)$$

$$\begin{aligned}
 \begin{cases}
 (b) - 2 \times (a) \\
 4A(\Delta x)^2 + 2B(\Delta x) = f_{i+2} - f_i \\
 2A(\Delta x)^2 + 2B(\Delta x) = 2f_{i+1} - 2f_i
 \end{cases} \\
 \Rightarrow 2A(\Delta x)^2 = f_{i+2} - f_i - 2f_{i+1} + 2f_i = f_{i+2} - 2f_{i+1} + f_i \\
 \Rightarrow A = \frac{f_{i+2} - 2f_{i+1} + f_i}{2(\Delta x)^2} \\
 \Delta x B = f_{i+1} - f_i - \frac{f_{i+2} - 2f_{i+1} + f_i}{2} = \frac{2f_{i+1} - 2f_i - f_{i+2} + 2f_{i+1} - f_i}{2} \\
 \Rightarrow B = \frac{-3f_i + 4f_{i+1} - f_{i+2}}{2\Delta x}
 \end{aligned}$$

So what do we got? A is equal to f i plus 2 minus twice f i plus 1 plus f i divided by 2 delta x square and B as minus 3 f i plus 4 f i plus 1 minus f i plus 2 divided by 2 delta x and C as f i. So, now if we want to find the values of the first derivative del f by del x del f by del x, so you know the polynomials, so you can write del f by del x del f by del x now you can write, so you have f x as A x square plus B x plus C. So, del f del x will be twice A x plus B.

So, that means, del f by del x at i, it will be 2 A x i plus B. So now, as x i is 0, so this x i is 0, x i is 0. So, this term will become 0. So, you will get equal to B, so it will be minus 3 f i plus 4 f i plus 1 minus f i plus 2 divided by 2 delta x. Now, similarly if you want to find the

second derivative then what do you write $\frac{d^2 f}{dx^2}$ will be twice A. So, if it is twice A, so, you can write so, $\frac{d^2 f}{dx^2}$ will cancel out it will be $f_{i+2} - 2f_i + f_{i-2}$ divided by Δx^2 .

So, at $\frac{d^2 f}{dx^2}$ at i . So, this is the way to find the polynomial. So, first you approximate the polynomials second order or third order polynomials, then you can write the coefficients you can find using the data of the dependent variable. So, putting which is in the at the origin that you can put x_i is equal to 0 and taking a uniform mix, x_{i+1} you can write as Δx and x_{i-1} you can write $-\Delta x$ and put all the values and find the constants A, B, C and once you know the polynomial, then you can find the derivatives $\frac{df}{dx}$ and $\frac{d^2 f}{dx^2}$.

So, now let us find the central difference approximation of first and second derivative of any function $f(x)$ by polynomial technique. So, for that purpose let us consider a second order polynomial $f(x)$ equal to $x^2 + Bx + C$ which has passed through three points $i-1$, i and $i+1$.

(Refer Slide Time: 34:46)

Second order polynomial
 $f(x) = Ax^2 + Bx + C$

$x_i = 0$
 $x_{i-1} = -\Delta x$
 $x_{i+1} = \Delta x$

$f_i = Ax_i^2 + Bx_i + C$
 as $x_i = 0$
 $C = f_i$

$f_{i-1} = A x_{i-1}^2 + B x_{i-1} + C = A (\Delta x)^2 - B \Delta x + f_i \dots (i)$
 $f_{i+1} = A x_{i+1}^2 + B x_{i+1} + C = A (\Delta x)^2 + B \Delta x + f_i \dots (ii)$

Add Eq. (i) and Eq. (ii)
 $f_{i+1} + f_{i-1} = 2A (\Delta x)^2 + 2f_i$
 $A = \frac{f_{i+1} - 2f_i + f_{i-1}}{2(\Delta x)^2}$

$\frac{df}{dx} \Big|_i = 2Ax_i + B = B = \frac{f_{i+1} - f_{i-1}}{2\Delta x}$
 $\frac{d^2 f}{dx^2} \Big|_i = 2A = \frac{f_{i+1} - 2f_i + f_{i-1}}{(\Delta x)^2}$

Eq. (ii)
 $f_{i+1} = \frac{f_{i+1} - 2f_i + f_{i-1}}{2(\Delta x)^2} (\Delta x)^2 + B \Delta x + f_i$
 $B \Delta x = f_{i+1} - f_i - \frac{f_{i+1} - 2f_i + f_{i-1}}{2}$
 $= \frac{2f_{i+1} - 2f_i - f_{i+1} + 2f_i - f_{i-1}}{2}$
 $B = \frac{f_{i+1} - f_{i-1}}{2\Delta x}$

So, let us consider second order polynomial, second order polynomial $f(x)$ equals to $Ax^2 + Bx + C$ and this is passing through three points. So, this is your i this is your $i+1$ and this is your $i-1$ and you have uniform step size Δx and let us assume the polynomial like this which is a second order polynomial.

So, this values is f_{i-1} , this values is f_i and this values f_{i+1} . So, now we let us considered the origin here, where x_i is equal to 0. So at this point, so this point it is Δx ,

so $x_i + 1$ will be Δx and $x_i - 1$ will be $-\Delta x$, because this point is the origin. So, this is your $-\Delta x$.

So, you can see that x_i is 0 , $x_i - 1$ is $-\Delta x$ and $x_i + 1$ is equal to Δx . So, now we can write f_i is equal to $A x_i^2 + B x_i + C$. But x_i is equal to 0 . So, this will be 0 , this will be 0 because x_i as x_i is equal to 0 . So, you will get C is equal to f_i .

So, similarly let us write f_{i-1} . So, you can write $A (x_i - 1)^2 + B (x_i - 1) + C$ because from this expression. Similarly, you can write f_{i+1} is equal to $A (x_i + 1)^2 + B (x_i + 1) + C$. So, already we have found the value of C because C is equal to f_i . So, let us put it there and put the values of $x_i - 1$ and $x_i + 1$ because $x_i + 1$ is equal to Δx and $x_i - 1$ is equal to $-\Delta x$.

So, if you write it so you will get so, $A \Delta x^2 - B \Delta x + f_i$ because $x_i - 1$ is $-\Delta x$ plus f_i . Similarly, here you will write $A \Delta x^2 + B \Delta x + f_i$, because C value of C is f_i . So, we have written this. Now, let us consider this is equation 1 and this is the equation 2.

So now add equation 1 and equation 2, so what you will get if you add it, so you will get $f_i + 1 + f_{i-1}$ is equal to., so this will be 2 into $A \Delta x^2$ and this term will get cancelled because you are adding so this is your minus this is your plus so it will get cancelled and you will get plus $2 f_i$.

So, from here you can write the value of A as $f_i + 1 - 2 f_{i-1} + f_{i-2}$ divided by $2 \Delta x^2$. So, now you find the value of B so, find the value of B from any equations. So, let us consider equation 2. So, if you consider equation 2, then you can write f_{i+1} is equal to $f_i + 1$.

So, this is the value of A divided by $2 \Delta x^2$ into $\Delta x^2 + B 2 \Delta x + f_i$. So, you find out the value of B . So, you can see these Δx^2 this Δx will get cancelled and you will, can write $B \Delta x$, $B \Delta x$ you can write as $f_i + 1 - f_{i-1} - f_{i-2} + 2 f_{i-1} - f_{i-2}$ divided by 2 .

So, then you will get 2 so it will be $2 f_i + 1 - 2 f_{i-1}$. So, here minus is there, so it will be $-\Delta x + 1 + 2 \Delta x - \Delta x - 1$. So, you can see that here this $2 \Delta x$ and $-\Delta x$ will get cancelled because it is plus here minus. So, finally, you will get B is equal to, so this is $2 \Delta x + 1$, so it will be $f_i + 1 - f_{i-1} - 1$ divided by $2 \Delta x$.

So, now, you see we have found the values of A, B and C. These constants C is this one B is this and A is this. So, now you can find the derivatives $\frac{df}{dx}$ and $\frac{d^2f}{dx^2}$. So, you can see from here that what will be your $\frac{df}{dx}$. So, from this expression you can see $\frac{df}{dx}$ at point i you can write twice $A x_i + B$ and x_i , what is the value of x_i ? x_i is 0.

So, you will get this is equal to B and this is your $f_{i+1} - f_{i-1}$ divided by $2\Delta x$. So, this is the central difference approximation of the first derivative and you know the order of accuracy is Δx^2 .

Similarly, now, you find the second derivative. So, $\frac{d^2f}{dx^2}$ at i . So, from this expression if you write $\frac{d^2f}{dx^2}$ is equal to so, you will get twice into A so, you will get twice A means say these $2 \cdot 2$ will get canceled. So, you will get $f_{i+1} - 2f_i + f_{i-1}$ divided by Δx^2 .

So, that you can see that this is the second order approximation of the second derivative using three points $i-1$, i and $i+1$ and we have use second order polynomial and found the values of constant A, B and C and we could find the derivative first derivative $\frac{df}{dx}$ and $\frac{d^2f}{dx^2}$ using three points f_i , f_{i-1} and f_{i+1} .

So, now let us write this forward difference, backward difference and central difference of first derivative, whatever we have derived using Taylor series expansion as well as general approximation and polynomial techniques.

(Refer Slide Time: 44:10)

$$\text{FD } \frac{\partial f}{\partial x} = \frac{f_{i+1} - f_i}{\Delta x} + O(\Delta x) \quad +1-1=0$$

$$\text{BD } \frac{\partial f}{\partial x} = \frac{f_i - f_{i-1}}{\Delta x} + O(\Delta x) \quad -1-1=0$$

$$\text{CD } \frac{\partial f}{\partial x} = \frac{f_{i+1} - f_{i-1}}{2\Delta x} + O[(\Delta x)^2] \quad -1-1=0$$

$$\text{FD } \frac{\partial f}{\partial x} = \frac{-3f_i + 4f_{i+1} - f_{i+2}}{2\Delta x} + O[(\Delta x)^2] \quad -3+4-1=0$$

$$\text{CD } \frac{\partial f}{\partial x} = \frac{f_{i+1} - 2f_i + f_{i-1}}{(\Delta x)^2} + O[(\Delta x)^3] \quad 1-2+1=0$$

$$\frac{\partial f}{\partial x} = \frac{f_{i+2} - 2f_{i+1} + f_i}{(\Delta x)^2} \quad 1-2+1=0$$

So, if you have seen that for first derivative we do the forward difference approximation what is that? $\frac{\partial f}{\partial x}$ is equal to $f_{i+1} - f_i$ divided by Δx and you know that it is the first order accurate. So, that means you have $i, i+1$ minus $i-1$. So, the value of f_{i+1} and f_{i-1} and these are uniform step size.

So, Δx and ΔX , so this is the forward difference approximation. Similarly backward difference approximation we have derived $\frac{\partial f}{\partial x}$ is equal to $f_i - f_{i-1}$ divided by Δx and you have seen that this is order of Δx and this is the order of Δx and central dependency you have used.

So, $\frac{\partial f}{\partial x}$ is equal to $f_{i+1} - f_{i-1}$ and divided by $2\Delta x$ and what is the order of accuracy it is order Δx^2 . Similarly, also we have derived using three points forward and backward and of this first derivative and we have shown that the approximation is second order accurate.

So, let us see that we have used $\frac{\partial f}{\partial x}$, is equal to $\frac{-3f_i + 4f_{i+1} - f_{i+2}}{2\Delta x}$. So, this is forward difference approximation and order of accuracy is Δx^2 . Similarly $\frac{\partial^2 f}{\partial x^2}$, we have used $f_{i+1} - 2f_i + f_{i-1}$ divided by Δx^2 , and what is the order of accuracy? It is order Δx^3 .

Similarly, $\frac{\partial^2 f}{\partial x^2}$ also you found using three points $f_{i+2} - 2f_{i+1} + f_i$ divided by Δx^2 . So, now let us see the coefficient of the values of f .

So, if you see the coefficient of f, f_i plus 1 and if you make the summation of coefficients it will be always 0.

So, you can see this is your plus 1 minus 1 is equal to 0, here also you can see, 1 minus 1 is equal to 0, this is also 1 minus 1 is equal to 0, here you can see minus 3 plus 4 minus 1 is equal to 0. Here also you can see 1 minus 2 plus 1 is equal to 0, here also 1 minus 2 plus 1 is equal to 0.

So, when you use some finite difference approximation and see the discretized this derivative first derivative second derivative the summation of the coefficient must be 0. So, to cross check whether your approximation is correct or not, you can sum up all the coefficient and check whether that is coming as 0.

So, if it is 0, so most probably your approximation may be correct. So, for any approximation, so, if you use the third derivative or fourth derivative of any derivative function and if you see that the approximate the finite difference approximation of it, the summation of all the coefficient must be 0.
