Biomicroelectromechanical Systems

Welcome back to this 10th lecture of BioMEMS. Just to review what we were talking in the last lecture, we try to generate an equation where in the free energy per mole of the system which is also expressed as $KT \ln \gamma_i$; γ_i being the arithmetic coefficient was equated to the total amount of work that was needed to bring a charge $Z_i e$ into minus $Z_i e$ into central ion of interest which is a plus $Z_i e$ charge. In other words, in order to give a charge its counter ionic cloud the amount of work done is given by this integral of $d w$. So, from the equation, we try to get an expression in terms of γ_i as the following.

(Refer Slide Time: 01:27)

The whiteboard contains the following handwritten equations and notes:

$$\ln \gamma_i = -\frac{z_i^2 \epsilon^2}{2DKT} \left(\frac{R}{1+kR} \right)$$
$$R = \left[\frac{4\pi \epsilon^2}{D KT} \sum N_i z_i^2 \right]^{1/2}$$

N_i → NO. of moles of different charges per unit volume on the part a^3 / cm³

C_i → M (moles/litre)

$$N_i = \frac{N C_i}{1000}$$
$$R = \left[\frac{8\pi \epsilon^2 N}{D KT 1000} \sum z_i^2 C_i \right]^{1/2}$$
$$\ln \gamma_i = -\frac{\epsilon^2}{2DKT} |z_+ z_-| \left[\frac{8\pi \epsilon^2 N}{D KT 1000} \sum z_i^2 C_i \right]^{1/2} \sqrt{R_i}$$
$$= -|z_+ z_-| \epsilon^2 \left[\frac{8\pi \epsilon^2 N}{D KT 1000} \sum z_i^2 C_i \right]^{1/2} \sqrt{R_i}$$

So, $\ln \gamma_i$, natural log of γ_i - the activity coefficient - also came equivalent to minus Z_i square epsilon square by twice DKT into the counter ionic radius k by 1 plus small k times of a - a here was the ion size parameter; it is an indication of the tentatively what is the size of the central ion of interest.

Also we know that k essentially is nothing but, 4π by D , E square by kT sigma $N_i Z_i$ square to the power of half. In other words, we can express this in a more appropriate manner by assuming that what is really N_i ?

(Refer Slide Time: 02:32)

$$\ln V_{\pm} = -\frac{z_{\pm}^2 E^2}{2DKT} \left(\frac{R}{1+K_a} \right)$$

$$R = \left[\frac{4\pi E^2}{DKT} \sum N_i z_i^2 \right]^{1/2}$$

$$N_i = \frac{N_i C_i}{1000}$$

$$\ln V_{\pm} = -\frac{E^2}{2DKT} |z_{\pm}| \left[\frac{8\pi E^2}{DKT} \frac{N}{1000} \right]^{1/2}$$

$$= -\frac{|z_{\pm}| E^2}{2DKT} \left[\frac{8\pi E^2}{DKT} \frac{N}{1000} \right]^{1/2}$$

N_i is essentially the number of moles of different charges whether it is positive or negative its different charges - you remember the way we talked about the subscript i in our lectures before - per unit volume on the point A. We were talking about a central ion and a point A, which was close by where the potential is ϕ and then a negative ion atmosphere, which was all the way around it just for recapitulating what we had done earlier. So this was the point A, essentially this here was the point A when which was at a distance of small a , from the center of this charge; this was the point A (Refer Slide Time: 03:26), the radius here is small a .

We can really express this in terms of the concentration of the various ions that are there in the solution and from which we formulate it, the mean concentration. What we try to estimate this as since C_i is also in terms of mole - molar or moles per liter - and this N_i was per centimeter cube because it was all CGS units which were used at the beginning of the 19th century to explain at least problems - majority of the problems - in this chemistry or related to charge essentially in chemistry.

Here, we could consider the number of moles per unit volume N_i to be a product of the Avogadro number N , which is 6.023×10^{23} the numbers in mole divide into the concentration C_i by 1000cc or 1000 centimeter cube makes 1 litre. From these two, from this kind of an expression the k could be written as really 8π by D epsilon

square by kT N by 1000 half $C_i Z_i$ square and this C_i is nothing but, the mean ion concentration of i . So, we can call it μ_i .

(Refer Slide Time: 05:14)

$$\ln \gamma_i = -\frac{z_i^2 \epsilon^2}{2DKT} \left(\frac{R}{1+ka} \right)$$

$$R = \left[\frac{8\pi \epsilon^2}{D} \frac{1}{KT} \sum N_i z_i^2 \right]^{1/2}$$

$$N_i = \frac{N C_i}{1000}$$

$$\ln \gamma_{\pm} = -\frac{\epsilon^2}{2DKT} |z_+ z_-| \left[\frac{8\pi \epsilon^2}{D} \frac{N}{KT} \frac{1}{1000} \sum z_i^2 \right]^{1/2} \sqrt{\mu_i}$$

$$= -\frac{|z_+ z_-| \epsilon^2}{2DKT} \left[\frac{8\pi \epsilon^2}{D} \frac{N}{KT} \frac{1}{1000} \sum z_i^2 \right]^{1/2} \sqrt{\mu_i} \frac{1}{1+ka}$$

Today, we try to go ahead in this and try to find out what this $\ln \gamma_i$ would be in terms of this final and full expression for k and we get that $\ln \gamma_i$. Now, I would like to change the subscript i by its essence the way that we had started all these things we had assumed i could be either positive or it could be negative.

So, I write γ_{\pm} here is equal to $\epsilon^2 / 2DKT$ times of Z_+ plus Z_- and modulus of that, so for the principle of electro neutrality the positive and negative charges and otherwise electrically neutral medium would be equal exactly opposite. Even if we do the total amount of positive and total amount of negative charge that would be same as reporting the square of the magnitude the charge. Of course, you have to take the magnitude of Z_+ plus Z_- times of k by $1 + k$ into a and k here comes out to be equal to 8π , let me just go ahead and shift this down a little bit so that it will be convenient.

So this is Z_+ plus Z_- mod times of k , which is 8π by D , ϵ^2 by KT , N by 1000 times of this is whole half of course, times of root of μ_i divided by $1 + ka$ the value of k again being 8π by D ϵ^2 by KT , N by 1000, whole half should be second bracket, whole half times of root μ_i times of a where a is the ion size parameter. This gives us very interesting way of representation, we could couple this all together and just write it as in the following manner; Z_+ plus Z_- of course, modulus and ϵ^2 is taken here, I think the value of 8π by D ϵ^2 by KT , N

by 1000 half root mu i and in the denominator you have twice DKT plus twice DKT times of 8 pi by D E square by KT, N by 1000 whole half root of mu i times of a.
 (Refer Slide Time: 08:47)

$$-\frac{1}{2} \sqrt{\mu} i = \left\{ \frac{Z_+ Z_- | A \sqrt{\mu}}{1 + B a \sqrt{\mu}} \right\}$$

$$A = \frac{\epsilon^2}{2.303} \left(\frac{2\pi N \epsilon^2}{1000 k^3} \right)^{1/2} \frac{1}{(DT)^{3/2}}$$

$$B = \left(\frac{8\pi N \epsilon^2}{1000 k} \right) \frac{1}{(DT)^{1/2}} K = -$$
 D of water / Exp. is to be done at
 $T = 298K$ $P = 1atm$ STP $N = 6.023 \times 10^{23}$
 $\epsilon = 1.6 \times 10^{-19} C$
 $A = 0.511$ & $B = 3.29 \times 10^{-7}$

Therefore, we can write this expression in a little different manner, so that it can be more simplified. You have minus log of gamma plus minus and you can write this as Z plus Z minus a times of root mu divided by 1 plus B times of, therefore, this can be represented as 1 plus B times of, a times of root of mu. These a s and B s are just it is like for overall convenience we can report this and if you really represent the whole thing in terms of a mind there is a log here which is equal to 2.303 ln, so 2.1 by 2.303 ln value.

Essentially A here is nothing but, square of E by 2.303 and I am just simplifying and writing it down, which is convenient 2 pi N epsilon square by 1000 k 3 this is just by simplification that you can represent this particular form with 1 plus b times a root mu and here Zi square times of a times of root of mu, Zi square is again modulus of Z plus into Z minus times. So, this raise to the power of half times of 1 by DT to the power of 3 by 2, that is how the A can be represented and B here in this equation can be represented as 8 pi N epsilon square by 1000 k times of 1 plus DT to the power half.

Interestingly, if we put the values of the dielectric constant for water, in most of the cases, the solutions which are being investigated is essentially an aqueous based solution of these ions. The basic medium there is water; the basic dielectric is water, so if we consider put the value of the dielectric constant D of water in these expressions A and B simultaneously and consider, the experiment to be done at STP, experiment to be done at Standard Temperature Pressure. So, 298 Kelvin 1 atmosphere pressure this kind of

condition and then of course, N value is a universally acclaimed fixed value 6.023×10^{23} to the power of 23 numbers of atoms or molecules or charges as in this case.

Therefore, we can calculate the values of A and B, if you look at and also the E here is 1.6×10^{-19} coulomb, charge of 1 electron. So, the A it kind of encompasses all these constant values you have a k value for the Boltzmann constant, you put the Boltzmann constant value 1000 N , you have E square and you have dielectric constant for water and temperature 298 Kelvin.

You can compute all these values and it comes out to be 0.511 and B comes out to be 3.29×10^7 relatively a very large value. But the very fact is that because, this B is also in product with ion size parameter which maybe a few nanometers and we will be investigating and estimating a few tables later on for the ion size parameter A. Therefore, the equation and the gamma value would hold consistency.

(Refer Slide Time: 12:36)

Therefore

$$-\log \gamma_i = \frac{A z_i^2 \sqrt{\mu}}{1 + B a \sqrt{\mu}}$$
 where $A = 0.511$
 $B = 3.3 \times 10^7$
 where a is the ion size parameter Table 7.1
 enlists the ion size parameters for use in Debye-Hückel equation.
 where

$$H = \frac{1}{2} \sum C_i z_i^2$$

Therefore, the whole equation can really be written down in the terms of minus log gamma i, as you are seeing here; equals A times of Z_i^2 Z_i is being the positive or the negative charge divided by $1 + B a \sqrt{\mu}$, where A is calculated to be 0.511, B is calculated to be 3.3×10^7 by assuming STP - Standard Temperature Pressure and the various parametric values for N Avogadro number, epsilon, electronic charge so on so forth.

So, a is very interesting proposition here, a as you see in this particular area here, a is the ion size parameter. So, it can be very well enlisted and some standard ion size parameters are listed here: if you can see here, selenium ions or tin ions of quadravalent state has an ion size parameter of about approximately 1100 pico meters. Similarly, you have H plus,

Al plus 3, Fe 3 plus and Cr minus these values they have about 900 pico meters. Essentially, these all ion size parameters have been investigated revaluated from the Debye Huckle theory and they are tabulated and they are used often on for all sorts of experiments.

Therefore, all the equations, all the parameters in this particular equation here for estimating the activity coefficient exist. You know what Z_i square is, you can calculate what the μ_i is the activity coefficient of the mean concentration of the particular solution is, and you know what A and B are. These are constants which are estimated by this STP conditions, Standard Temperature Pressure conditions. Therefore, ion size parameter if we borrow it from this table, which has been probably estimated by experiments, can be used very well to calculate what the activity of a particular ion of interest, while you are doing the deduction protocol.

(Refer Slide Time: 14:59)

Having said that, let us actually look into a little bit of a kind of solved example were we talk about how to calculate the activity of sodium and sulfate ions independently. Let us say, 0.01 molar solution of sodium sulfate. You have a case, were you have a sodium sulfate solution and you would like to find out the activity coefficient of sodium and sulfate ions independently or individually by looking at the Debye Huckle set of equations.

(Refer Slide Time: 14:59)

SOLVED EXAMPLE

Calculate the activity of the sodium & sulfate ions in a 0.01M solution of sodium sulfate.

Ans The ionic strength of 0.01M Na_2SO_4 solution is calculated as below:

$$I_i = \frac{1}{2} \sum C_i Z_i^2$$

$i = \text{Na}^+, \text{SO}_4^{2-}$

$$I_i = \frac{1}{2} [2(0.01) \times (1)^2 + (0.01) \times (-2)^2]$$

$$= 0.03 \text{ M}$$

$a_{\text{Na}^+} =$

$$-\log \gamma_{\text{Na}^+} = \frac{0.511 \times (+1)^2 \times \sqrt{0.03}}{1 + 3.3 \times 10^7 \times 4 \times 10^{-8} \times \sqrt{0.03}} = 0.0719$$

$\text{B}_{100}\text{O}_{100}^{100-}$	100

Let us try to solve this, we have a case where we need to find out the activity given the ionic strength or given the molarity of the sodium sulfate solution. The ionic strength of the sodium sulfate of the 0.01 molar Na_2SO_4 sodium sulfate solutions is calculated as below you have half $C_i Z_i^2$. How many i s are there, there is a Na plus and there is a SO_4 minus 2 so there are 2 i s. So, μ_i in this case would be half of concentration of Na plus which is essentially 0.02 molar, so 2 into 0.01 the sodium sulfate solution has a molarity mind you of 0.01.

There are 2 sodium ions every molecule of Na_2SO_4 and therefore, you have the overall molarity of Na plus as 0.02 molar. The concentration times of the square on the valency which is plus 1 in case of sodium plus and this is essentially a summation term because it

is accumulative of all the positive and negative charges. Now, you have the concentration for SO_4 which is only 1 molar or which is only 1 in the molecule. So you have a concentration of 0.01 molar times of, now the charge here is minus 2 because SO_4 or sulfate ion bivalent ion essentially square of that, so this comes out to be from calculations equal to 0.03 molar. So, this is the mean ionic strength of this sodium sulfate solution.

Once the mean ionic strength is calculated rest of the things are easy. You just need to calculate minus log of gamma Na plus in this case, which would be equal to the 0.511 the a term, terms of times of the square of the valency on the sodium which is plus 1 square times of root over mu i; where mu i is 0.03 molar and divided 1 plus B which in this case is 3.3 into 10 to the power of 7 times of the ion size parameter of Na plus which can be obtained from the table as given before here. The sodium Na plus essentially if you look at this particular zone here has an ion size parameter of about 400 pico meters or 4 into 10 to the power of minus 10 meters or 4 into 10 to the power of minus 8 centimeters.

Since we are actually using the CGS units for calculating everything here, we would take the ion size parameter A as 4 into 10 to the power of minus 8 centimeters times of the root of 0.03 molar. This comes out to be equal to 0.0719 that is what the ionic strength of the negative log of the ionic activity of Na plus is; so let us calculate and do the same kind of calculation for the SO_4 ion.

(Refer Slide Time: 19:54)

Handwritten calculations on a whiteboard:

$$-\log \gamma_{\text{SO}_4^{2-}} = (0.511) \times (-2)^2 \times \sqrt{0.03} = 0.271$$

$$\gamma_{\text{SO}_4^{2-}} = 4 \times 10^{-8} \text{ cm} \left[1 + 3.3 \times 10^7 \times 4 \times 10^{-8} \times \sqrt{0.03} \right]$$

$$\therefore \gamma_{\text{Na}^+} = 0.847$$

$$\gamma_{\text{SO}_4^{2-}} = 0.516$$

Activities of both the ions

$$a_{\text{Na}^+} = \gamma_{\text{Na}^+} \times c_{\text{Na}^+} = 0.847 \times 0.02 \text{ M} = 1.69 \times 10^{-2} \text{ M}$$

$$a_{\text{SO}_4^{2-}} = \gamma_{\text{SO}_4^{2-}} \times c_{\text{SO}_4^{2-}} = 0.516 \times 0.01 \text{ M} = 5.16 \times 10^{-3} \text{ M}$$

In case of SO_4 , the activity can be, the equation can be written down as minus log gamma SO_4 minus 2 equal to 0.511 that is the A parameter, A aspect, the coefficient A

times of square on the valency of sulfate and sulfates valency is minus 2, so square on minus 2 times of root over 0.03 molar divided by 1 plus the B constant which is 3.3×10 to the power 7 times of the radius of SO_4 ion which again through this particular figure. Here SO_4^{2-} and Na^+ are more or less in the same size domain is about 400 pico meters.

Essentially, it means the ion size parameter a , for SO_4^{2-} should be about 4×10 to the power minus 8 centimeters as before. Mind you again, this all these equations are in terms of CGS units, so apart from the molarity which is standard universal unit the other components of the equation has essentially CGS corresponding units centimeter gram second unit. So this comes out to be 4×10 to the power minus 8 times of root of 0.03 and essentially that is calculated to be 0.2876.

Taking antilog on the both equations solved earlier the activity of the sodium ion comes out to be 0.847 and the activity of the sulfate ion SO_4^{2-} in this case comes out to be 0.516. If we look at these are the activity coefficients; let me just reiterate the activity coefficient of the sodium ion comes out to be 0.847 and the activity coefficient of the SO_4 ion comes out to be a 0.516. Now if you want to look at really the activities of both the ions which is also known as a Na^+ and this a is probably the activity do not confuse it with the ion size parameter.

Let us just get a different name here for convenience. Let us say, we have we just write a_i instead of a_{Na^+} equals γ_i times of x_i as you know x_i is the ionic concentration of the particular analyte. In case of sodium you have 0.847 as the γ_i and the x_i as you know in this case because you have 2 atoms per molecule and the overall concentration is 0.01. For sodium the concentration is 0.02 molar.

The activity in this case is only about 1.69×10 to the power of minus 2 molar and in case of SO_4 the activity SO_4^{2-} can be the γ , SO_4^{2-} times of concentration of SO_4^{2-} , which is 0.516 to above times of 0.01 molar. Mind you in 1 molecule there is only 1 SO_4 atom which is present; therefore, its concentration is only same as that of the Na_2SO_4 solution. This comes out to be equal to 5.16×10 to the power of minus 3 molar. That is how you are able to calculate the activity of Na^+ and SO_4^{2-} in a sodium sulfate solution by looking at the various aspects.

Now, what you would be interested to look at here is that if you may just see that the activities of both are different. Therefore, Na^+ is a more active ion than SO_4^{2-} , so in such kind of situations if there is a presence of both ions that is Na^+ and SO_4^{2-}

minus there is a tendency of the electrode to be heavily interfered by the Na plus ion if you are detecting sulfate ions.

You have to be careful in order to create a situation where the Na plus ion is blocked in a manner, so that its activity is also blocked and the ion selective electrode can only specifically pickup; So 4 minus ion in the presence of Na plus ion minus 2 ion in case of a So 4, minus 2 ion in place of or in the presence of Na plus ion.

You have a fairly good idea about activity coefficients at this time and how they would be calculated. Once, we are actually done with these activity coefficients what is very important to find out here is that, due to these activities what is really the change in the EMF the measured potential of such a solution, where you have about more than 1 species of ions with interfering ions as well as the primary ion of interest.

Essentially the E value, the potential value, would change because of these participating in other kind of interfering kind of ions. There is a set of equations called Nicolskii-Eisenmann equation which is used for predicting the EMF value of j such components together in a solution - in an electrochemical solution and the effects of those components on the measured EMF of such a solution.

(Refer Slide Time: 25:56)

Ion Selectivity Coefficient

- Ion selective electrodes respond to particular ions and nearly all are subjected to interference from other similar ions.
- The interference can be quantified and is normally provided with the literature that the ion selective electrodes are supplied with.
- The extent of interference is expressed in the Nicolskii-Eisenmann equation as a selectivity coefficient.

$$E = K + S \log(a_i + K_{ij} a_j^{n_i/n_j})$$

where a_i is the primary ion & its charge is n_i
 and a_j is the secondary ion & its charge is n_j
 When other ions interfere the Nernst equation can be modified to

$$E = K + S \log(a_i + K_{ij} a_j^{n_i/n_j} + K_{ik} a_k^{n_i/n_k} + K_{il} a_l^{n_i/n_l})$$

where K_{ij} , K_{ik} , K_{il} etc are the selectivity coefficients for j th, k th, l th ... ions respectively.

For designing ion selective electrodes, the very important factor is the ion selectivity coefficient and so it is a kind of quantification of the interference. In a nutshell, we can summarize all this as that ion selective electrode responds to particular ions and nearly all are subjected to interference from other similar ions. The interference can be quantified is normally provided with a literature that ion selective electrodes are supplied

with and the extent of interference is expressed by this set of equations Nicolskii-Eisenmann equation as a selectivity coefficient.

The EMF of given out by such a solution which has more than 1 ion of a participating ions with 1 ion of interest and the remaining interference ions can be also written as K plus $S \log$ of a_i which is the activity of the primary ion of interest plus k_{ij} and this is called the ion selectivity coefficient. This is a measured quantity and I will be demonstrating, I will be just showing a table which we will be talking about several such values of k_{ij} , which means that the selectivity coefficient for a j th interfering ion for i primary ion of interest. So i here is the primary ion of interest and the j here is the interfering ion, so selectivity coefficient is in the presence of j interfering ion. What would be the selectivity coefficient of j over i ; the primary ion of interest that is how the selectivity coefficient is defined.

(Refer Slide Time: 25:56)

Ion Selectivity Coefficient

- Ion selective electrodes respond to particular ions and nearly all are subjected to interference from other similar ions.
- The interference can be quantified and is normally provided with the literature that the ion selective electrodes are supplied with.
- The extent of interference is expressed in the Nicolskii-Eisenmann equation as a selectivity coefficient.

$$E = K + S \log(a_i + k_{ij} a_j^{z_i/z_j})$$

where a_i is the primary ion & its charge is z_i
 and a_j is the secondary ion & its charge is z_j
 When other ions interfere the Nernst equation can be modified to

$$E = K + S \log(a_i + k_{ij} a_j^{z_i/z_j} + k_{ik} a_k^{z_i/z_k} + k_{il} a_l^{z_i/z_l} + \dots)$$

where $k_{ij}, k_{ik}, k_{il}, \dots$ etc are the selectivity coefficients for j th, k th, l th ions respectively.

Times of a j which is the activity of the j th ion, which is the interfering ion divided by n by z ; n is the charge of a_i or the primary ion of interest and z is the charge of the secondary ion or the interfering ion j in this case. The derivation of this equation of course, is a not within the scope of this course but, it does give a very good fairly good accurate estimate of the modified EMF in the presence of a j th phase of ion which is interfering. So if you have several such interfering species, by the by, this is again a linear equation if you look at it pretty in linear if you do not consider this bracketed term here or if you consider this to be just the differential concentration it is still a straight line with an intercept and Nernstian slope S . When other ions interfere that means there are more than 1 ions which are interfering in that case the equation will slightly change still

it will be in the Nernst equation form but, it will be modified to E equals K plus S log of a i plus k ij a j to the power of n by z a j.

Again let me reiterate here, n is the charge or the valancy of the primary ion i of interest here, z a j is the charge or the valancy of the secondary ion or the interfering ion j in this case plus k ik a k times a k to the power of n by z a k plus k il a l due to the power of n by z a l so on so forth up till all the phases are covered. This is essentially an extension of multiple terms of the same series here that we showed before for expressing the modified EMF in the presence of an interfering ion.

(Refer Slide Time: 30:18)

Some Selectivity coefficients for Ion Selective electrodes

Ion	Range (M)	Selectivity coefficients k_{ij}
Fluoride	10^{-6} - 10^{-1}	$k_{OH^-} = 0.1$, $k_{Cl^-} = 0.001$, $k_{Br^-} = 0.001$, $k_{I^-} = 0.001$, $k_{NO_3^-} = 0.001$, $k_{HCO_3^-} = 0.001$, $k_{H_2PO_4^-} = 0.001$, $k_{HPO_4^{2-}} = 0.001$, $k_{SO_4^{2-}} = 0.001$, $k_{CO_3^{2-}} = 0.001$, $k_{S^{2-}} = 0.001$, $k_{O^{2-}} = 0.001$, $k_{H^+} = 0.001$, $k_{Na^+} = 0.001$, $k_{K^+} = 0.001$, $k_{NH_4^+} = 0.001$, $k_{Ca^{2+}} = 0.001$, $k_{Mg^{2+}} = 0.001$, $k_{Ba^{2+}} = 0.001$, $k_{Sr^{2+}} = 0.001$, $k_{Pb^{2+}} = 0.001$, $k_{Cd^{2+}} = 0.001$, $k_{Zn^{2+}} = 0.001$, $k_{Ni^{2+}} = 0.001$, $k_{Co^{2+}} = 0.001$, $k_{Mn^{2+}} = 0.001$, $k_{Fe^{2+}} = 0.001$, $k_{Cu^{2+}} = 0.001$, $k_{Ag^{2+}} = 0.001$, $k_{Hg^{2+}} = 0.001$, $k_{Li^+} = 0.001$, $k_{Rb^+} = 0.001$, $k_{Cs^+} = 0.001$, $k_{NH_4^+} = 0.001$, $k_{Mg^{2+}} = 0.001$, $k_{Ca^{2+}} = 0.001$, $k_{Ba^{2+}} = 0.001$, $k_{Sr^{2+}} = 0.001$, $k_{Pb^{2+}} = 0.001$, $k_{Cd^{2+}} = 0.001$, $k_{Zn^{2+}} = 0.001$, $k_{Ni^{2+}} = 0.001$, $k_{Co^{2+}} = 0.001$, $k_{Mn^{2+}} = 0.001$, $k_{Fe^{2+}} = 0.001$, $k_{Cu^{2+}} = 0.001$, $k_{Ag^{2+}} = 0.001$, $k_{Hg^{2+}} = 0.001$, $k_{Li^+} = 0.001$, $k_{Rb^+} = 0.001$, $k_{Cs^+} = 0.001$, $k_{NH_4^+} = 0.001$

For example k_{OH^-} for hydroxide in the presence of F^- ion electrode is 0.1

This means that for a concentration of Hydroxide 10 times higher than fluoride would give a response double that of fluoride alone.

The value of k_{ij} would come from the Nernst equation

$E_1 = K + S \log [a_i] \quad \text{--- (1)}$

$E_2 = K + S \log [a_i + k_{ij} a_j^{z_i/z_j}] \quad \text{--- (2)}$

$E_2 - E_1 = S \log \left[\frac{a_i + k_{ij} a_j^{z_i/z_j}}{a_i} \right]$

$k_{ij} = \left[\frac{a_i \cdot 10^{(E_2 - E_1)/S} - a_i}{a_j^{z_i/z_j}} \right] / a_i^{z_i/z_j}$

So k_{ij} , k_{ik} , k_{il} etcetera are the selectivity coefficients of the jth, kth, ith phase coefficients for the jth, kth, ith ions respectively. Essentially, if you look at some of the typical examples of k_{ij} values it can be very apparently it is really mentioned in this table 4.1 here (Refer Slide Time: 30:30), which talks about the ranges and selectivity coefficients of some ion selective electrodes. Essentially if you want to measure a fluoride ion, we were talking about these different selectivity coefficients and let me actually take you back into the slide again.

The ranges and selectivity coefficients of some selective electrodes ion selective electrodes are mentioned in this table here 4.1. How to interpret this table really? This here is giving the k_{ij} value, so if you want to measure hydroxide which is the primary ion in this case. In the presence of fluoride the ion selectivity of hydroxide is only 0.1, if you want to measure bromine and iodine chlorides really must be absent from the solution so that you could measure bromine and iodine.

However, if you want to measure chlorine there is a selectivity coefficient especially bromides are present. Similarly, hydroxides in the presence of bromides will offer a k_{ij} value which is written in this table so on so forth. Therefore, this table really is a summary of what would be the selectivity of a primary ion of interest over the several interfering ions which are mentioned here in this extreme left column of this particular table. The selectivity coefficients are independently mentioned here or individually mentioned here in the third column of this particular table.

Let us also look at what the interpretation of this would be, so if the k_{ij} for hydroxide in the presence of fluorides is 0.1, it would mean that for a concentration of hydroxide 10 times higher than the fluoride, it would give a response double that of the fluoride alone. If the hydroxide is about 10 times more than the fluoride then there would be a response which is double that of the fluoride alone, so which is of some measurable significance. Therefore, you are measuring it also means that if you are measuring fluoride and if you have hydroxide you need not bother till and until the hydroxide is about 10 times more in concentration than the fluoride is.

For example k_{ij} for hydroxide in the presence of F^- ion electrode is 0.1

This means that for a concentration of Hydroxide 10 times higher than fluoride would give a response double that of fluoride alone.

The value of k_{ij} would come from the Nicolskii-Eisenmann Equation

$$E_1 = K + S \log [a_i] \quad \text{--- (1)}$$

$$E_2 = K + S \log [a_i + k_{ij} a_j^{1/2}] \quad \text{--- (2)}$$

$$E_2 - E_1 = S \log \left[\frac{a_i + k_{ij} a_j^{1/2}}{a_i} \right]$$

$$k_{ij} = \left[\frac{a_i \cdot 10^{(E_2 - E_1)/S}}{a_j^{1/2}} \right] / a_i^{1/2}$$

Let us also look at one more aspect, how to determine the value of k_{ij} and I would like to do some derivations here. When we were talking about the Nicolskii-Eisenmann equation the value of k_{ij} would come from the Nicolskii-Eisenmann equation. Let us suppose, we have certain ion of interest i for which the EMF has been measured using the Nernstian equation as E_1 is equal to K plus Nernstian slope S times of log activity of the primary ion a_i . When we add a secondary ions let us say, j with a selectivity coefficient k_{ij} , E_2 here can be represented as K plus S log of a_i plus $k_{ij} a_j$ to the

power of n by z ; suppose n and z are of course, the valences on ion i , and ion j respectively.

So, if you just try to calculate k_{ij} here it could come out from subtracting equations 2 from 1 and we can get E_2 minus E_1 is $S \log$ of a_i plus $k_{ij} a_j$ to the power n by z by a_i . Here, this is actually the modified activity, let us assume that this modified activity is a_i dash; this is no longer a_i because a_i is the activity of the ion in presence of none other and a_i dash is the modified activity of the ion in the presence of the phase j .

If you solve this equation and trying to find out what k_{ij} is from this equation; k_{ij} can be written down as a_i times of 10 to the power of E_2 minus E_1 divided by S minus a_i dash divided by a_j to the power of n by z that is what k_{ij} would be in this case; a_i dash again I reiterate is actually the modified or corrected activity of the mixed solution. Let me write it down somewhere that in this particular case a_{ij} a_i dash is modified activity in presence of ion j .

Since, we have more or less covered how to calculate the activity of a particular ion of interest in a solution and also we have seen a methodology for calculating the selectivity coefficient. Now let us do a practical example wherein we have let us say, two participating solutions and we have a data of the EMF from the pure solution as well as the mixed phase, were both the solutions are participating both the ions are participating. We try to calculate what the k_{ij} or the selectivity coefficient would be.

(Refer Slide Time: 36:46)

SOLVED EXAMPLE

For a calcium ISE, the calibration slope S was $+29.6 \text{ mV/decade}$ in a 0.001 M solution.

In a 0.001 M calcium chloride solution, the cell potential was -20.1 mV , while the potential in a mixed solution containing 0.001 M CaCl_2 and 0.1 M NaCl was -19.8 mV . Calculate the selectivity coefficient of Ca^{+2} ions in the presence of Na^+ .

$K_{\text{Ca}^{+2}, \text{Na}^+}$

Pure Sol. \rightarrow $V_{\text{Ca}^{+2}} = \frac{RT}{zF} \ln(C_{\text{CaCl}_2})$

Mixed Sol. \rightarrow $V_{\text{Ca}^{+2}} = \frac{RT}{zF} \ln \left[\frac{(0.001)^2 + (0.002)(-1)^2}{2} \right]$

$\frac{RT}{zF} \ln \left[\frac{(0.001)^2 + (0.002)(-1)^2}{2} \right] = \frac{RT}{zF} \ln \left[\frac{0.003 \text{ M}}{2} \right]$

$\frac{RT}{zF} \ln \left[\frac{(0.001)^2 + (0.1)^2}{2} \right] = \frac{RT}{zF} \ln \left[\frac{0.1 \text{ M}}{2} \right]$

$= 0.163 \text{ M}$

Let us look at the solved example here. Let us suppose that for calcium ISE for a calcium ion selective electrode the calibration slope S is essentially plus 29.6 milli volts per decade; this word decade essentially means 1 order of concentration. The concentration

strength, of pure solution and also mixed solution. So, ionic strength of CaCl₂ half C_i Z_i square C_i here is 0.001 if it is a pure solution times of plus 2 square the charge on the calcium or the valency on the calcium is plus 2 plus CaCl₂. So there are 2 chlorine atoms per molecule of CaCl₂ and so the chlorine concentration would be exactly double 0.002 molar times of minus 1 square, this comes to be 0.003 molar. So this is the ionic strength of the pure solution which is needed to calculate the gamma Ca plus 2 pure.

Let us also calculate the ionic strength of the mixed solution, which has CaCl₂ and NaCl both phases. We have half times of and the concentration of CaCl₂ is 0.001 molar as reported in the mixed solution with plus 2 square, plus 0.002 for the chlorine times of minus 1 square plus again 0.1 times of 1 square, 1 being the valency on the NaCl plus 0.1 times of minus 1 square and this comes out to be effectively equal to 0.103 molar. So I_m for CaCl₂ comes out to be 0.003 molar and for a mixed solution the mean ionic strength comes out to be 0.103 molar. After doing this, let us find out that in pure solutions, what the activity coefficient of the Ca plus 2.

(Refer Slide Time: 41:50)

In pure sol. $\gamma_{Ca^{+2}}$

$$-\log \gamma_{Ca^{+2}}^{pure} = \frac{0.511 \times (2)^2 \times \sqrt{0.003}}{1 + 3.3 \times 10^7 \times 6 \times 10^{-8} \sqrt{0.003}}$$

$$= 0.1008$$

$$\gamma_{Ca^{+2}}^{pure} = 0.793$$

$$a_{Ca^{+2}}^{pur} = 0.793 \times [0.001 M]$$

$$= 7.93 \times 10^{-4} M$$

 The activity coefficient of Ca²⁺ in the mixed sol.

$$-\log \gamma_{Ca^{+2}}^{mixed} = \frac{0.511 \times (2)^2 \times \sqrt{0.103}}{1 + 3.3 \times 10^7 \times 6 \times 10^{-8} \sqrt{0.103}}$$

$$\gamma_{Ca^{+2}}^{mixed} = 0.3978$$

$a_{Ca^{+2}} = 0.3978 \times 0.001$
 $= 3.978 \times 10^{-4}$
 activity of Ca²⁺ in M

In pure solution the activity coefficient of Ca plus 2 can also be represented by the following. Minus log of gamma Ca plus 2, let us indicate this as pure equals 0.511 which is the parameter A which we calculated before plus Z_i square. In this case, it is plus 2 square the valency on calcium is plus 2 times of root over the mean ionic strength, which was found out from the earlier equation to be 0.003 molar divided by 1 plus 3.3 10 to the power 7, which is also the value of the B parameter in the particular equation into we have to really locate what is the ion size parameter in this case and if you just go back and look into what that parameter is.

The ion size parameter for calcium plus 2 ions as you can see here in this case, is close 600 pico meters, so it is about 600 pico meters. So 6×10^{-8} centimeters again I would like to reiterate that all these system of equations is based on CGS units. We need to take the value in centimeters, so 6×10^{-8} is the ion size parameter A in this case times root of 0.003 the mean ionic strength. So this comes out to be equal to 0.1008.

Essentially taking antilog on both sides the gamma value or the selectivity coefficient of the pure Ca plus 2 comes out to be equal to 0.793 as in this particular case. In pure solution therefore, if we see what is the ionic activity of the calcium plus 2 ions so the a_i value for the Eisenmann equation it comes out be equal to $a_{Ca^{+2}}^{pure}$ the gamma Ca^{+2} pure times of the concentration in this case is 0.001 molar. So, it comes out to be 7.94×10^{-4} molar, that is what the activity of the pure calcium ions is in a pure solution.

(Refer Slide Time: 41:50)

In pure sol. $\gamma_{Ca^{+2}}$

$$-\log \gamma_{Ca^{+2}}^{pure} = \frac{0.511 \times (2)^2 \times \sqrt{0.003}}{1 + 3.3 \times 10^7 \times 6 \times 10^{-8} \sqrt{0.003}}$$

$$= 0.1008$$

$$\gamma_{Ca^{+2}}^{pure} = 0.793$$

$$a_{Ca^{+2}}^{pure} = 0.793 \times [0.001 M]$$

$$= 7.94 \times 10^{-4} M$$

 The activity coefficient of Ca^{+2} in the mixed sol.

$$-\log \gamma_{Ca^{+2}}^{mixed} = \frac{0.511 \times (2)^2 \times \sqrt{0.103}}{1 + 3.3 \times 10^7 \times 6 \times 10^{-8} \sqrt{0.103}}$$

$$\gamma_{Ca^{+2}}^{mixed} = 0.3978$$

$a_i = 0.3978 \times 0.001$
 $= 3.978 \times 10^{-4}$
 activity of Ca^{+2} in mixed sol.

Let us simultaneously find out, what is a_i dash. That means, the activity of the calcium plus 2 ions in the presence of Na plus. In order to do that in the second phase of this question we need to actually see, what is the activity coefficient for Ca in the mixed solution? We find out the activity coefficient of Ca plus 2 in the mixed solution. We have in the mixed solution minus log of gamma Ca^{+2} and let us call this phase mixed phase equals 0.511 which is the a parameter times of plus 2 square again, because z is plus 2 essentially into or a product multiplied by the mean ionic strength in the mixed phase which is 0.103 as calculated before, if you remember, divided by 1 plus 3.3×10^7 to the power of 7 which is the B parameter times of again the calcium ion of course, has the

ion size parameter of 600 pico meters which we just deciphered a moment back last slide was 6 into 10 to the power minus 8 times of root of 0.103.

The gamma Ca plus 2 in the mixed phase in this manner comes out to be equal to 0.3978 and if you look at or the a i dash value that means, the activity of Ca plus 2 in presence of Na plus that comes out to be equal to essentially 0.3978 times 0.001 which is also the molarity of the CaCl 2 in the mixed solution and that is 3.987 into 10 to the power of minus 4 molar. So that is what the mixed activity or activity of Ca plus 2 phases in the mixed solution.

Going to the second part of the problem, let us find out, what is the a j value; that is the j in this case being the sodium plus ion or Na plus ion the a j value essentially is the activity of the Na plus or the presence of Ca plus 2, so we calculate that here.

(Refer Slide Time: 47:20)

Calculating the activity of interfering Na^+

$$-\log \gamma_{\text{Na}^+ \text{ mixed}} = \frac{0.511 \times (1)^2 \times \sqrt{0.103}}{[1 + 3.3 \times 10^{-7} \times 4 \times 10^{-8} / \sqrt{0.103}]}$$

$$= 0.11497$$

$$\gamma_{\text{Na}^+ \text{ mixed}} = 0.7674$$

$a_{\text{Na}^+ \text{ mixed}} = 0.7674 \times 10^{-3} = 7.674 \times 10^{-4}$

$K_{\text{Ca}^{+2}, \text{Na}^+}$

$$a_{\text{Ca}^{+2} \text{ pure}} (10)^{\frac{E_2 - E_1}{5}} = a_{\text{Ca}^{+2} \text{ mixed}}$$

$$E_2 = -19.8 \text{ mV}$$

$$E_1 = -20.1 \text{ mV}$$

$$= \frac{(7.93 \times 10^{-4} \times (10)^{0.3/2.6} - 3.978 \times 10^{-4})^{2/1}}{(7.67 \times 10^{-4})^{2/1}}$$

$$= 0.0705$$

Calculating in the next phase, the activity of the interfering ion here the a i dash, a i, a j are all according to the Nicolskii-Eisenmann equation, which we had discussed just about 2 3 slides back. Essentially, the interfering ion here is Na plus so for the Na plus we have minus log gamma Na plus in the we call it mixed again because the Na plus is present only in the mixed solution is equal to 0.511 A parameter times of Z square. Z in this case is plus 1 because Na has a univalent ion, so Na plus is a univalent so plus 1 square times of root of the mu which is again it does not get altered, mean ionic remains same in the mixed solution 0.103 whole under the root and this is actually divided by 1 plus 3.3 10 to the power minus 7 which is the B parameter times of the value of Na or the ion size parameter of Na which is about 400 pico meters from the table as we had done

before. So, this is 4×10^{-8} centimeters again the CGS units have to be used root over 0.103 and this comes out to be equal to 0.11497.

Therefore, the γ_{Na^+} in the mixed phase or the activity coefficient of the sodium ion in the mixed phase comes out to be 0.7674 or the activity of the sodium ion a_{Na^+} in the mixed phase comes out to be equal to 0.7674 into 0.1 which is 7.67×10^{-2} molar. That is what the activity of γ_{Na^+} in the mixed phase is, so this is corresponding to also a j .

(Refer Slide Time: 47:20)

Calculating the activity of interfering Na^+

$$-\log \gamma_{\text{Na}^+ \text{ mixed}} = \frac{0.511 \times (1) \times \sqrt{0.103}}{[1 + 3.3 \times 10^7 \times 4 \times 10^{-8} \sqrt{0.103}]}$$

$$= 0.11497$$

$$\gamma_{\text{Na}^+ \text{ mixed}} = 0.7674 \quad a_{\text{Na}^+ \text{ mixed}} = 0.7674 \times 0.1 = 7.67 \times 10^{-2}$$

$K_{\text{Ca}^{2+}, \text{Na}^+}$

$$= \frac{a_{\text{Ca}^{2+} \text{ pure}}^{0.3/29.6} \left(\frac{E_2 - E_1}{S} \right)^{2/1}}{\left(\frac{a_{\text{Na}^+ \text{ mixed}}}{7.67 \times 10^{-2}} \right)^{2/1}}$$

$$= \frac{(7.93 \times 10^{-4} \times (10))^{0.3/29.6} - 3.778 \times 10^{-4}}{(7.67 \times 10^{-2})^{2/1}}$$

$$= 0.0705$$

We have pretty much everything which we need for Nicolskii-Eisenmann equation solution and we need to find out what the ion selectivity coefficient of K^+ over Na^+ in the mixed phase and that can come out by the equation a i which is a Ca^{2+} pure if you remember correctly, the activity of Ca^{2+} pure times of 10 to the power of $(E_2 - E_1) / S$. If you remember from the question earlier, the E_2 was given as minus 19.8 milli volts that is the potential generated by measurement along the mixed phase or the mixed solution and E_1 the potential on the pure solution was given as minus 20.1 milli volts.

$(E_2 - E_1) / S$ really is nothing but, 0.3 divided by 29.6. Therefore, this 10 to the power $(E_2 - E_1) / S$ minus a i dash which is the modified activity of Ca^{2+} that means this is the mixed phase activity divided by a j which is to the power n by z and a j here is the activity of the Na^+ mixed phase to the power of n by z ; n is plus 2 mind you because this is valancy of Ca^{2+} primary ion of interest and z is the valancy of the secondary ion or the interfering ion as 1 as in case of Na^+ .

(Refer Slide Time: 47:20)

Calculating the activity of interfering Na^+

$$-\log Y_{\text{Na}^+}^{\text{mixed}} = \frac{0.511 \times (1)^2 \times \sqrt{0.103}}{[1 + 3.3 \times 10^7 \times 4 \times 10^{-8} \sqrt{0.103}]}$$

$$= 0.11497$$

$$Y_{\text{Na}^+}^{\text{mixed}} = 0.7674$$

$K_{\text{Ca}^{+2}, \text{Na}^+} = \frac{a_{\text{Ca}^{+2}}^{\text{pure}} (10)^{\frac{E_2 - E_1}{S}}}{a_{\text{Na}^+}^{\text{mixed}}}$

$E_2 = -19.8 \text{ mV}$
 $E_1 = -20.1 \text{ mV}$

$$= \frac{(7.93 \times 10^{-4} \times (10)^{\frac{0.3}{29.6}} - 3.978 \times 10^{-4})}{(0.7674 \times 10^{-2})^{2/1}}$$

$$= 0.0703$$

So, if you put back all the values here it comes out to be equal to 7.93×10^{-4} to the power of minus 4 times 10 to the power of 0.3 divided by 29.6 minus 3.978×10^{-4} , these values have been all calculated earlier, if you may recall divided by this 7.67×10^{-2} times to the power of 2 by 1 that is 2 this comes out to be equal to 0.0703 . So that is what the $K_{\text{Ca}^{+2}, \text{Na}^+}$ in the presence of the interfering ion Na^+ is going to be.

What really it means is that, the solution containing almost 14 times as much Na^+ as Ca^{+2} would give a response to which is double that of the value for Ca^{+2} ions alone. Definitely, Na^+ ion is weakly interfering ion to Ca^{+2} . In conclusion, what I would like to ascertain here is that in these kinds of problems, you get a very good idea or a very good feel of what would be the level of interference of a certain ion over a primary interest and this is definitely very helpful for designing ion selective electrodes.

So, we are almost towards the end of this lecture and I would like to discuss again what we would take up in the next lecture. We have now by and large seen detailed derivations about ionic activity, understood and realized the importance of how it is helpful in designing ion selective electrodes and also how we can predict the EMF of a solution which has all these mixed phase ions of different kind with some interfering some primary ions of interest.

(Refer Slide Time: 47:20)

Calculating the activity of interfering Na^+

$$-\log Y_{\text{Na}^+}^{\text{mixed}} = \frac{0.511 \times (1)^2 \times \sqrt{0.103}}{[1 + 3.3 \times 10^7 \times 4 \times 10^{-8} \sqrt{0.103}]}$$

$$= 0.11497$$

$$Y_{\text{Na}^+}^{\text{mixed}} = 0.7674$$

$a_{\text{Na}^+}^{\text{pure}} = 0.7674 \times 10^{-2}$
 $a_{\text{Na}^+}^{\text{mixed}} = 7.67 \times 10^{-4}$

$K_{\text{Ca}^{+2}, \text{Na}^+}$

$$a_{\text{Ca}^{+2}}^{\text{pure}} (10) \frac{E_2 - E_1}{S} = a_{\text{Ca}^{+2}}^{\text{mixed}}$$

$$E_2 = -19.8 \text{ mV}$$

$$E_1 = -20.1 \text{ mV} = \frac{(7.93 \times 10^{-4} \times (10)^{0.3/29.6}) - (3.778 \times 10^{-4})}{(7.67 \times 10^{-2})^{2/1}}$$

$$= 0.0705$$

Now, coming to some physically realizable electrodes etcetera, the natural question is that can we really look at some of the sensors more closely and how the mechanisms helps to sense things like gases or things like certain metabolites or chemicals. These sensors are often on used in medical diagnostics area where problems related to increase in urea within the blood or increase in blood glucose etcetera are quickly recorded and sent almost real time investigation is sometime done on the bedside as we have been talking out in our earlier lectures before.

In the next lecture, I would like to cover more or less some details about, what is that interface of some of these sensors with the different metabolites of interest related to human body, human blood or some other gases which may be effective for designing a gas sensor eventually. Then, we would like to look at how we can further miniaturize them to have an electrochemical response and understand how in a MEMS way in a micro engineering manner or using micro engineering tools we could develop something sensitive to detect and pickup analyses of interest. So, I would like to close this lecture with this.

Thank you
