

Bio – Microelectromechanical Systems

Prof. Shantanu Bhattacharya

Department of Mechanical Engineering

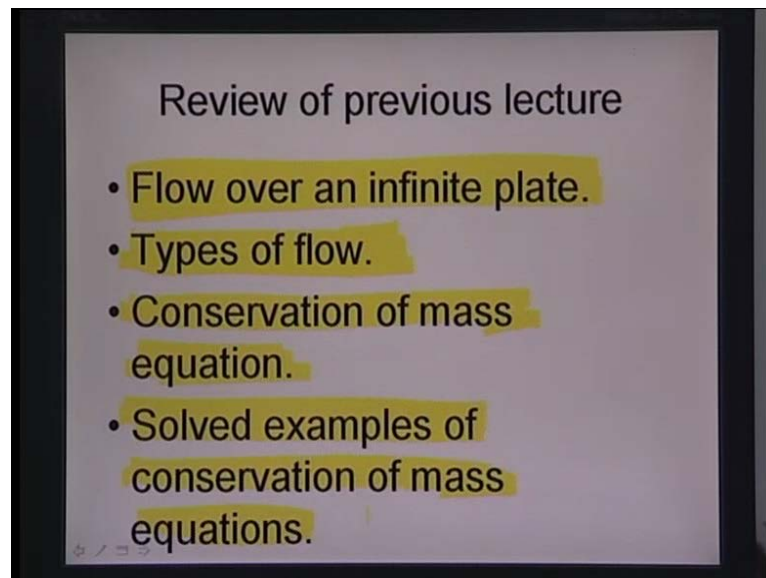

Indian Institute of Technology, Kanpur

Module No. # 01

Lecture No. # 28

Hello and welcome back to this 28th lecture on Bio-Microelectromechanical systems. Let us begin with a quick preview of what we have done last time.

(Refer Slide Time: 00:23)

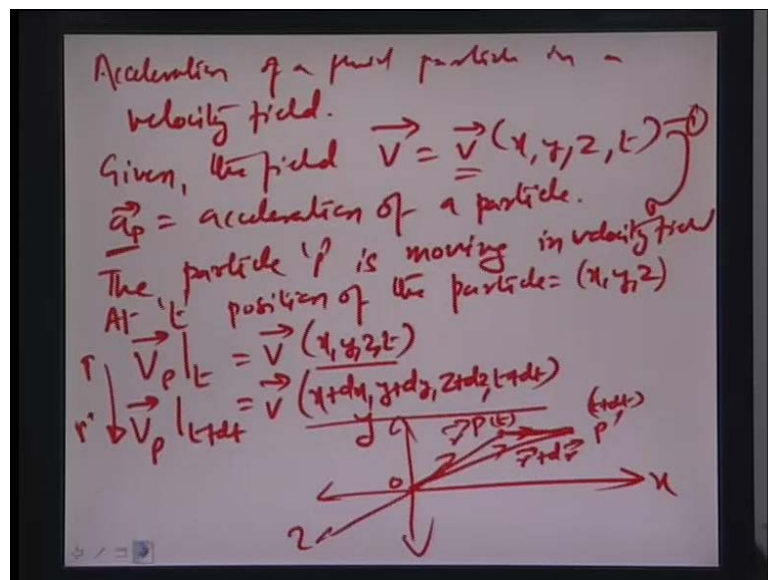

We talked about the flow over an infinite plate; the way that the boundary layer would be created as a difference between the fully developed region of the flow and the layer adjacent to the plate, which has shear deformation. We talked about different types of flows regarding 1, 2, 3 dimensional flows and tried to calculate the velocity fields. We also discussed about a control volume dx, dy, dz and tried to derive the conservation of mass equation, which is also the first Navier-Stokes equation. We solved examples for ascertaining the velocity component or the density with respect to time or space for compressible and incompressible flows. Again to recollect, compressible flows are those, where density changes with time. Incompressible are those, where the density does not change as a function of time.

Today, we will try to derive the conservation of momentum equation, which is also known as the second Navier-Stokes equation. Essentially, all this theory is very important because when we translate this theory to the micro scale, the interesting part is that the mass transport becomes time independent. It essentially reveals, if there are two side by side flowing streams of fluid in a micro channel, the seldom x because owing primarily because of this reason

If we look at how to derive the conservation of momentum, there is something to do with acceleration of a fluid particle. Newton's second law of force is nothing but mass into acceleration. So, let us first calculate the acceleration of a fluid particle in a velocity field.

(Refer Slide Time: 02:36)

Given the field v as a function of x , y , z and space-time, let us assume a p is the acceleration vector of a fluid particle. So, we want to find out what a_p is in terms of velocity. Let us say, the particle p is moving in the velocity field as represented here above in equation 1. At time t , the particle is at position x , y , z . So, let us say at t position of the particle is x , y and z . This particle has a corresponding velocity at that point in space at time t , which is represented by v_p at t equals v into x , y , z , t .

Let us say, it has a velocity at t plus dt , which is represented as x plus dx , y plus dy , z plus dz , t plus dt . Essentially, what it really means is that you have this rectangular coordinate system with x , y and z components. You have a radius vector r , somewhere

here at point p with respect to the origin o. This changes to another point p dash and the new radius vector becomes r plus dr. Essentially, this is the position at time t, this is the position as t plus dt. The vector connecting these two is the position vector; the particle has traversed from point p to p dash. It is definitely a function of x plus dx. This point here is x plus dx and that means the traversing of the particle in the x direction is by an elemental distance dx. The traversing of the particle in the y direction, but this path is being executed. So, it there are three components of this path. The particle traverses dy and similarly the traversing of the particle in the z direction, the particle traverses dz from point p to p dash. There are two different time instances, t and t plus dt. If we consider or if we try to find out what is the change in velocity as the particle moves from p to p dash.

(Refer Slide Time: 06:32)

$$\begin{aligned} d\vec{v}_p &= \frac{\partial \vec{v}}{\partial x} dx_p + \frac{\partial \vec{v}}{\partial y} dy_p + \frac{\partial \vec{v}}{\partial z} dz_p + \frac{\partial \vec{v}}{\partial t} dt \\ \vec{v} &= u\hat{i} + v\hat{j} + w\hat{k} \\ \frac{d\vec{v}_p}{dt} &= \frac{\partial \vec{v}}{\partial x} \left| \frac{dx_p}{dt} \right| + \frac{\partial \vec{v}}{\partial y} \left| \frac{dy_p}{dt} \right| + \frac{\partial \vec{v}}{\partial z} \left| \frac{dz_p}{dt} \right| + \frac{\partial \vec{v}}{\partial t} \\ \frac{dx_p}{dt} &= u, \quad \frac{dy_p}{dt} = v, \quad \frac{dz_p}{dt} = w \\ \vec{a}_p &= \frac{d\vec{v}_p}{dt} = u \frac{\partial \vec{v}}{\partial x} + v \frac{\partial \vec{v}}{\partial y} + w \frac{\partial \vec{v}}{\partial z} + \frac{\partial \vec{v}}{\partial t} \end{aligned}$$

If we consider or if we try to find out what is the change in velocity as the particle moves from p to p dash, the velocity dv_p can be effectively written as the rate of change of the velocity vector p with respect to x times of dx plus dx p because x p is the position vector or the x component of the position vector at of the particle p. So, dv vector by dx is the rate of change of velocity in the x direction of the particle times of dx p plus rate of change of velocity of the particle with respect to y times of dy p plus rate of change of the velocity of the particle with respect to z times of dz p.

You have a time component here; the time is varying with respect to t . So, the rate of change of velocity vector of the particle with respect to t times of dt . So, this is how the differential element of velocity dv_p can be written from v_p . If we differentiate this with respect to time, we will have dv_p vector with respect to dt . It is essentially the rate of variation of v with respect to x times of dx . These are again special components, so it should have only dx . Suppose your v vector comprises of three components u , v and w . Therefore, u really is differentiable only with respect to x and not with time. This is how you basically represent the velocity vector. At the position p , the vector is invariant. So, $\frac{dv_p}{dt} = \frac{dv_p}{dx} \frac{dx}{dt} + \frac{dv_p}{dy} \frac{dy}{dt} + \frac{dv_p}{dz} \frac{dz}{dt}$. This is essentially your rate of change of velocity vector of particle p with respect to t .

Now, we know $\frac{dx}{dt}$ is nothing but the velocity of the particle in the x direction, $\frac{dy}{dt}$ is the velocity of the particle in the y direction and $\frac{dz}{dt}$ is the velocity of the particle in the z direction. We can represent them by u , v and w . Essentially, the acceleration vector is nothing but the $\frac{dv_p}{dt}$, the rate of change of velocity vector of particle p with respect to t is nothing but $u \frac{dv_p}{dx} + v \frac{dv_p}{dy} + w \frac{dv_p}{dz}$. Why we did not use the chain rule here for differentiation by taking the derivative of dv by dx ? Because v is essentially $v(t)$ at a certain time point t .

Again, let me just repeat this point once more (Refer Slide Time: 10:01); v vector is the velocity at time point t and it changes to the velocity at time point $t + dt$ later on. This is essentially x, y, z and t and this is related to $x + dx, y + dy$ and $z + dz$ plus times of $t + dt$. So, once you have differentiated this vector with respect to x . The time component is automatically gone out. As time is concerned, the differentiation of v with respect to x is independent of time and therefore, the first component is not differentiated with respect to time. The second component is a representative of the position of a particle x_p . What we are doing here is $\frac{dx_p}{dt}$, which means it is a instantaneous velocity of the particle in the x direction, when it is at position p .

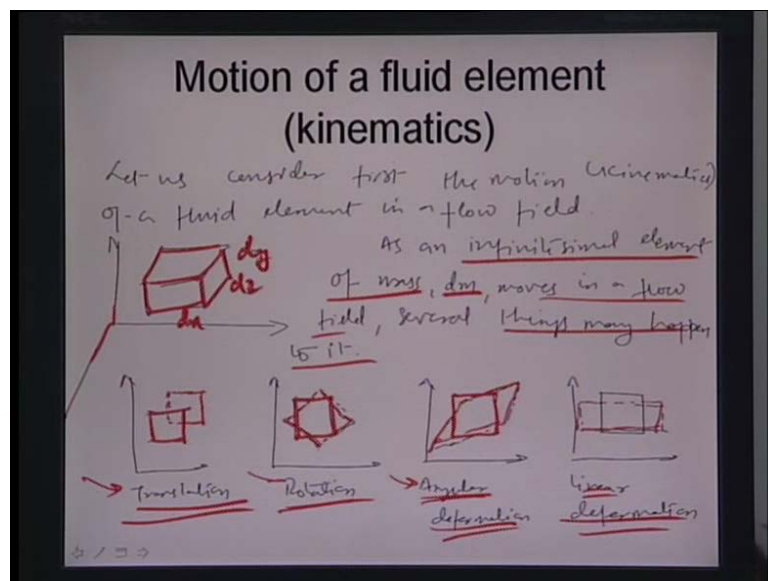

Similarly, $\frac{dy_p}{dt}$ is essentially a representative of the instantaneous velocity of the particle in the y direction, when it is resting at p . So, these are essentially nothing but u, v and w . V is already independent of t , so it is a constant as far as differentiation with respect to t is concerned. Here is the new term, which comes out. x_p can of course be differentiated with respect to t and this gives the instantaneous velocity of the particle in

the y direction, in the x direction at the point p. This is how this equation emerges out of acceleration from the previous equation.

So, acceleration of the particle can be represented as $u \frac{dv}{dx} + v \frac{dv}{dy} + w \frac{dv}{dz}$. I may just quickly rub this and write this again. This is what the acceleration vector a_p is and of course, there is a $\frac{dv}{dt}$ and the velocity of v with respect to time t .

Thus, you have defined the acceleration. The fluid may be accelerated, as it is convected into a region of higher velocity. Let us look at that; suppose you have a rectangular block of fluid, what kind of forces that block will feel because of stresses, which are taking place in the medium with respect to that control volume? If you look at the type of deformations that such a small control element would have in a shearing stream, assuming the volume to be present somewhere in the stream, the kinematics of such a mechanism can be illustrated as shown in this particular figure.

(Refer Slide Time: 13:17)

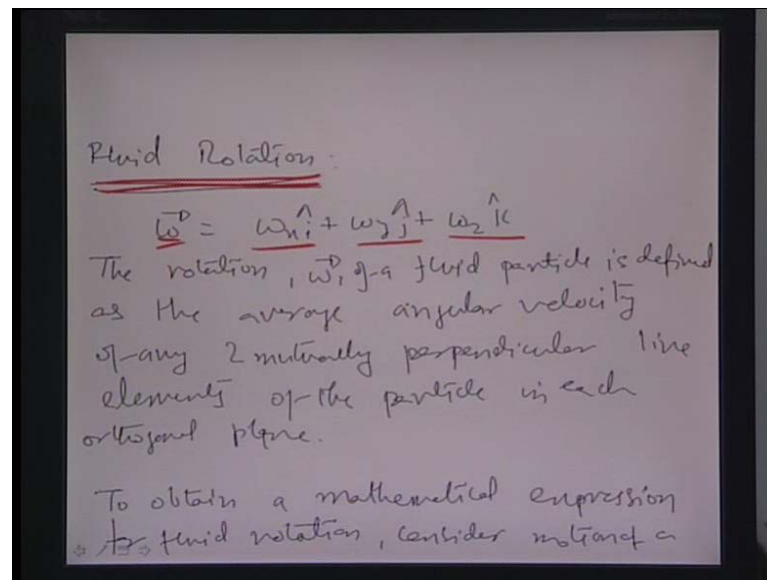

This is the box present in a rectangular coordinate system. The volume element has a volume of dx, dy, dz . Essentially, this is an infinite decimal element of mass dm , where ρ is the density. We assume the density ρ is to be constant. It is an incompressible flow, so $\rho dx, dy, dz$.

Essentially, the total mass of this small volume element is called dm and it moves in a flow field. So, the number of deformations or the number of kinematics states of a block is simply translated. It means that this was really the initial position of the block. It changes to this new position here. So, this is simply translated motion. It may rotate, which means that the block is integral in shape or not changing or losing its shape. It rotates at the same point; it may deform, which means that the block actually starts changing its shape from a square to more like a parallelogram. Something like this or it may actually deform linearly. This is linear deformation and that means a cube will become a cuboid because of volume continuity. Increase the length of the block by pulling it together. The area of cross-section will definitely decrease.

There are four different kinds of kinematics states that this block can have while moving in a fluid volume. One is translatory and another is rotary. As you can see here, third is angular deformation, where you are actually trying to compress the block and make a square into a parallelogram. The fourth is linear deformation, where you are actually trying to pull the block and trying to decrease cross section and increase length.

Consider the first aspect that is fluid rotation, how this small fluid element would be rotated? So, let us assume that ω is the angular velocity of rotation. If you again recall, the rotation is actually a block at one angle and one position. It actually rotates about its own place retaining the center, goes to a different location and rotates to a different location.

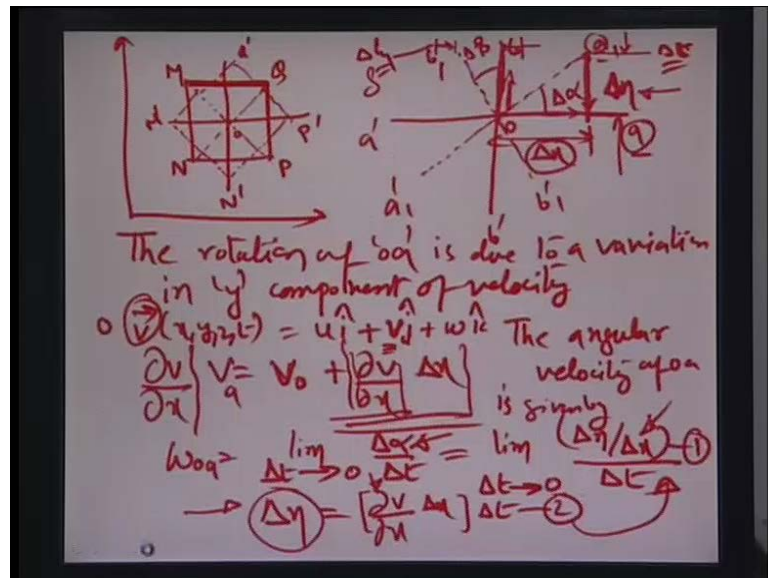

(Refer Slide Time: 15:50)

Let us assume angular velocity as ω . So, ω will again have three components: $\omega_x i$, $\omega_y j$ and $\omega_z k$, which means that these ω s have different axis and they have independent rotations. How do you define the rotation in this kind of a case? Suppose, you have two mutually perpendicular planes like this. You are rotating the planes all together retaining the perpendicularity between them. It means the planes are not really deforming along its own with respect to each other.

They are just keeping in the same angle and then trying to rotate in the average velocity of rotation. In this case, it would be nothing but the velocity of plane 1 plus velocity of plane 2, which is orthogonally placed by two planes. This is how you do the average velocity of rotation of average angular velocity of rotation of two mutually perpendicular line elements of the particles in each orthogonal plane. Let us obtain a mathematical expression for this. It will be a generic expression because it is later on translated to the case, where the angle between the plane changes as the rotation goes on and it is also the case of shear deformation; it is the third case.

(Refer Slide Time: 17:17)

Let us actually look at their aspect. In this particular case, you have a coordinate system x y. We are just considering rotation only in two-dimensional plane. You have a block somewhere in position O. These are the two diagonals of the block. The block rotates in a position, where basically these diagonals come like this. There is a new location of the box created because of this rotation in this manner.

Basically, you have the block placed at coordinates M, N, P and Q. Now, the new position coordinates become M dash, N dash, P dash and Q dash. It rotates about the center O. This rotation can be figured out in terms of two angles. The angle, which is in plane 1, it is able to define while it rotates and plane 2 - M Q, which is able to define as it rotates.

In other words, we can also consider two diagonals, which are perpendicular to these planes. They have a fixed angular relationship with respect to the plane. We consider the rotation of the two diagonals. In order to consider the average velocity of rotation in this particular instance, let us assume and proceed. So, you have a case, where you have diagonals intersecting at point O. In the first instance and after rotation, these diagonals change positions to the new value, where the perpendicularity between the diagonals is maintained; it is a case of pure rotation.

Let us call these with different names. Let this be o a, o a dash and this be o b and b dash. Essentially, these move to new positions a 1, a dash 1 and b 1, b dash 1. The rotation

vector is definitely related to the angles that these two planes would move in. Let us assume this angle to be $\Delta\alpha$, this as $\Delta\beta$. Let us also assume that the amount of distance that this particular plane $o a$ moves, as it goes to a_1 is $\Delta\eta$. The distance is about Δx and essentially, here again, the distance that this position b_1 is spaced from this position b is $\Delta\zeta$.

Let me just rewrite this a little. So, essentially, as the diagonal has moved by $\Delta\beta$, the position here was b . Before this, it is b_1 and the distance between b_1 and b is given $\Delta\zeta$. So, this is $\Delta\eta$ the distance between a and a_1 and the distance between b and b_1 is given by $\Delta\zeta$. So, these are some of the presumptions that we make to find out the relationship between the angles and the velocities. One important point to be considered here is that the rotation of vector $o a$ at this particular line is that $o a$ is due to a variation in y component of velocity.

Suppose, this particular point o is having or is defined by a velocity vector $v(x, y, z, t)$, where v in the x direction is given by u_i , v in the y direction is given by v_j and that in the z direction is given by w . Let us say the small v here represents the velocity in the y direction. There is definitely going to be a change of this velocity from point o in this particular region 2. At this point a , the velocity is different. If you assume that change to be Δv , this is small v and mind this is not the v vector. Here, it is Δv by Δx .

We can assume that the velocity at o in the y direction is v_0 , the velocity at a would be equal to v_0 plus Δv times Δx times of Δv by Δx times of Δx . So, this is the additional velocity, which is coming by the variation of the y component of the velocity when move from o to a in this particular rotation case. So, the angular velocity of $o a$ is really given by the rate of change of angle. Limit of Δt tends to 0 into $\Delta\alpha$ by Δt . We assume that two points a and a' are placed by a time point or they are placed in time by a difference of Δt .

So, $\Delta\alpha$ by Δt is the angular velocity - $\omega_{o a}$ at this particular instance of time. Therefore, this can also be represented by limit Δt tends to 0. What is $\Delta\alpha$? It is equal to nothing but $\Delta\eta$ by Δx . We assumed this to be the length of the arc. This distance is $\Delta\eta$ to the length of the arc. We assumed the radius vector to be Δx . So, the angle $\Delta\alpha$, which it moves is $\Delta\eta$ divided by the radius vector Δx .

This is essentially delta alpha divided by delta t. Let us now try to figure out what this quantity becomes or what is the relationship between the rate of change of velocity and the y component of the velocity with respect to x that we derived that is delta eta. Again, it would be nothing but the differential velocity change of v. The y component of the velocity goes from y o to a, which is nothing but delta v by delta x times of delta x divided by or into times of delta t, the time that it takes for this point to go from a to a 1.

The distance that the point a covers in order to go from a to a 1 is nothing but the differential change in the y velocity with respect to x times of delta x. This is the change or due to which the velocity at point a is different than the point o. This change times of delta t that is delta eta would be the amount of distance that a traverses to a 1. Let us say this is number 2 and this is equation 1. If I put this value of delta eta from equation 2 to equation 1, let us see what the value of omega o a finally becomes.

(Refer Slide Time: 26:06)

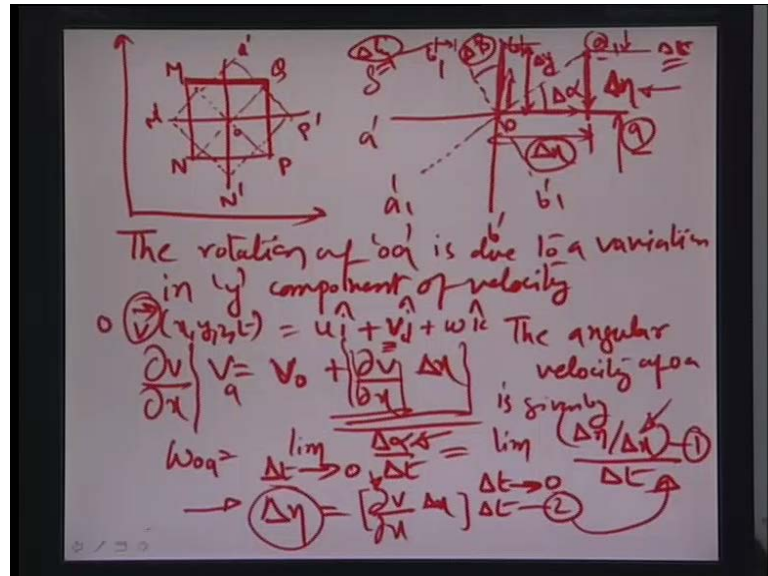

$$\omega_{oa} = \lim_{\Delta t \rightarrow 0} \left\{ \frac{\left(\frac{dv}{dx} \right) \Delta x \frac{\Delta t}{\Delta x}}{\Delta t} \right\} = \frac{dv}{dx}$$
 Angular velocity of the arm oa

$$\omega_{oa} = \left| \frac{dv}{dx} \right|$$
 Rotation of the line \overline{ob} , of length dy

Omega o a is limit delta t tends to 0 times of delta v by delta x times of delta x times of delta t by delta x divided by delta t. It is nothing but **dv by dx**. So, this essentially is dv by dx into delta x into delta t. It is basically the delta eta value divided by delta x divided by delta t. So, this comes out to be dv by dx. Omega o a or the angular velocity of the arm o a comes out to be equal to delta v by delta x. The rotation really translates into a rate of change of y velocity with respect to the x direction. If I do the same thing for the other component of the diagonal, which was in the y direction, we may need to ascertain

what is the change in the x direction or what is the change in the x velocity, y direction as it goes along y. What is the change in the x velocity? It would essentially be omega o b.

(Refer Slide Time: 28:01)

So, let us derive that expression as well. The rotation of the line o b of length delta y and it has become too crowded here. You can say that this (Refer Slide Time: 28:09) from here to here. This distance is delta y and you can also say that this distance is delta zeta. The angle moved is delta beta. So, there is a similar kind of relationship to describe omega o b.

(Refer Slide Time: 28:30)

$\omega_{oa} = \lim_{\Delta t \rightarrow 0} \left\{ \frac{\left(\frac{\partial v}{\partial x} \right) \Delta x \frac{|\Delta z|}{\Delta t}}{\Delta t} \right\} = \frac{\partial v}{\partial x}$

Angular velocity of the arm oa
 $\omega_{oa} = \left| \frac{\partial v}{\partial x} \right|$

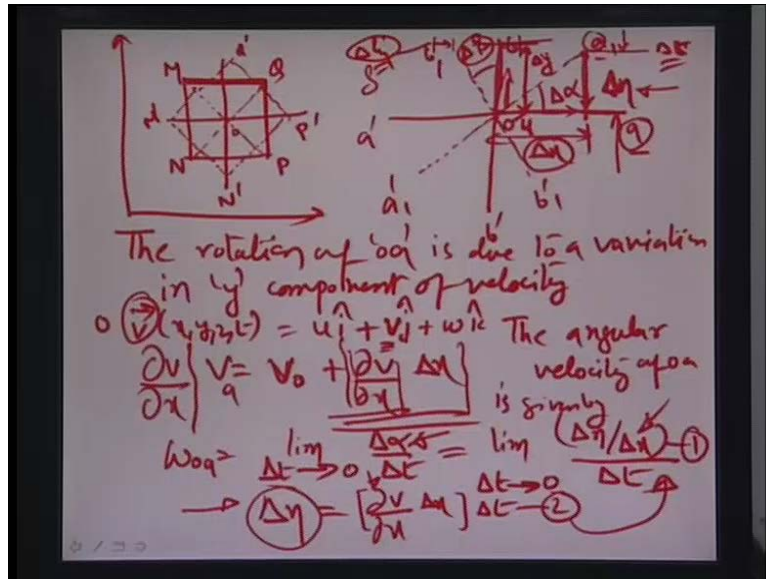

Rotation of the line ob of length Δy
 $\omega_{ob} = \lim_{\Delta t \rightarrow 0} \frac{\Delta \beta}{\Delta t} = \lim_{\Delta t \rightarrow 0} \frac{\Delta z_y / \Delta y}{\Delta t} \quad u = u_0 + \frac{\partial u}{\partial y} \Delta y$

$\Delta z_y = \left(-\frac{\partial u}{\partial y} \right) \Delta y$

There is a similar kind of relationship to describe ω_{ob} and you can write that as limit of $\Delta \beta$ by Δt . This can further be expressed as limit of Δz_y by Δy by Δt . Further, we have the velocity x at the origin. Here, the velocity is in the opposite direction and it is $u_0 + \frac{\partial u}{\partial y} \Delta y$ times of Δy .

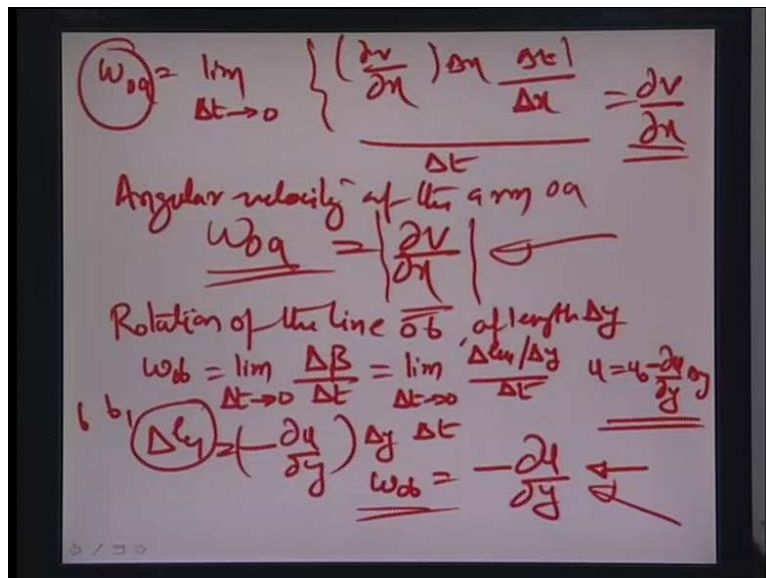

So you have let us say u is equal to $u_0 + \frac{\partial u}{\partial y} \Delta y$, pretty much in the similar manner as we did for the x variation. We are doing the y variation in this particular case. So, the Δz_y in this case is nothing but minus Δu by Δy . This is actually minus because it will be in the reverse direction. So, essentially this would be minus.

(Refer Slide Time: 29:58)

As you see here in this figure, u is in this direction, but delta u by delta x is the differential because of this rotation in the opposite direction. The value here would be u minus delta u by delta x times of delta y delta u by delta y times of the delta y. So, this is opposite to the direction of the positive u that you have taken.

(Refer Slide Time: 30:30)

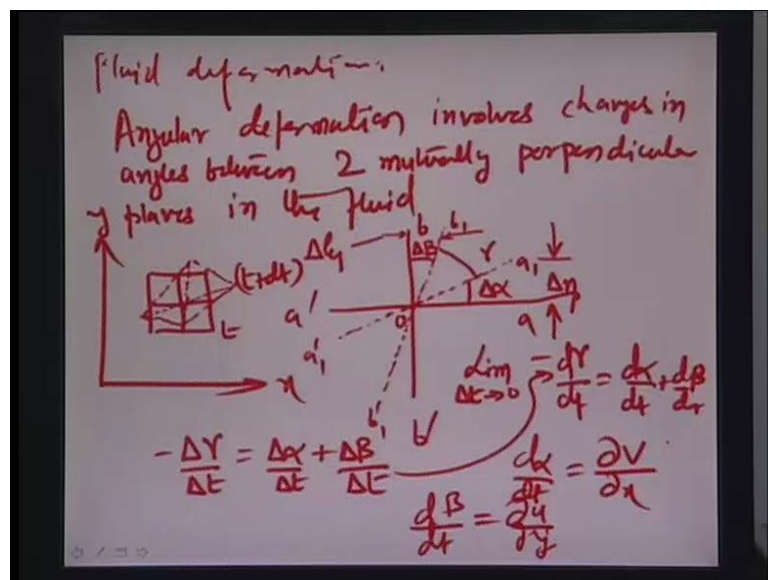

Now, we are left with delta zeta equal to minus delta u by delta y times of delta y times of delta t and the amount of distance that b takes to move to b prime or b 1. Therefore, omega o b in this particular case would be nothing but minus delta u by delta y in a

pretty much similar manner, as we did before for the x component. Therefore, we found out that omega of the two arms or the diagonals of the two arms are dv by dx and du by dy with the minus sign.

So, this is a very interesting derivation. We will keep this in mind for proceeding ahead with the momentum equation. So, this is what the rotational component would do. So, anything related to shear, which causes such a rotational component would essentially give you values in terms of dv by dx and minus du by dy .

(Refer Slide Time: 31:30)

Now, let us look at what is fluid deformation. Case 2 is regarding fluid deformation. Let us just refer back to that particular diagram here (Refer Slide Time: 31:40). Fluid deformation is this second case angular deformation. As you can see, the element actually changes its shape from regular square into a more like a quadrilateral or a parallelogram. Basically, there is a relative angular change between the two perpendicular planes. They do not remain at 90 degrees because the fluid moves.

Let us actually calculate using mathematics. What is this angular deformation? Angular deformation involves change in angle between two mutual perpendicular planes in the fluid. You have x and y coordinates here, you have a square with two diagonals. You are angularly deforming this, so that the new shape assumes that the diagonals moved away from perpendicular to this new angular shape.

Essentially, you are doing deformation in the particular shape. What essentially you are doing is that there is a diagonal $o a$, $o b$, $o a \text{ dash}$, $o b \text{ dash}$ direction and these diagonals are actually now changing in the $o a_1$, $o b_1$, $o b \text{ dash}_1$, $o a \text{ dash}_1$ direction. Let us assume that we have two angles, which is similar to the last case, it was $\delta \alpha$ and $\delta \beta$. Let us also assume that the distance between a and a_1 becomes $\delta \eta$. The distance between b and b_1 becomes $\delta \zeta$. We also assume another angle γ , which is in between. It is your $\delta \gamma$, what really is $\delta \gamma$? It is γ and not the $\delta \gamma$. This angle is γ and any change in this angle is $\delta \gamma$. It is negative; the angle is decreasing as you go along with time. so, $-\delta \gamma$ is nothing but $\delta \alpha$ plus $\delta \beta$. If you just divide the whole by δt assuming that this shape was at time instance t and this shape came at t plus dt . So, there is a time interval of δt in between or dt in between. You get $-\delta \gamma$; $\delta \gamma$ by δt is equal to $\delta \alpha$ by δt plus $\delta \beta$ by δt . so, taking limits on both sides as δt approaches 0, this whole expression becomes $-\frac{d\gamma}{dt}$ equal to $\frac{d\alpha}{dt}$ plus $\frac{d\beta}{dt}$. So, this is what angular deformation would really mean.

As we already know from earlier derivations that $\frac{\delta \alpha}{\delta t}$ or $\frac{d\alpha}{dt}$ is nothing but the rate of change of the y velocity in the x direction. Similarly, $\frac{\delta \beta}{\delta t}$ or $\frac{d\beta}{dt}$ is nothing but $\frac{\delta u}{\delta y}$ or the change in x velocity in the y direction. We have just done these two proofs. If you can recollect that in the last slide, we were trying to see the rotation of a component without deformation. In this case, there is a rotation and deformation simultaneously happening. Actually, the rotation is happening because of the deformation of the two sides.

(Refer Slide Time: 36:58)

The image shows a whiteboard with handwritten mathematical equations in red ink. The equations are as follows:

$$\left\{ \begin{aligned} -\frac{d\gamma}{dt} &= \frac{d\alpha}{dt} + \frac{d\beta}{dt} = \frac{\partial v}{\partial x} + \frac{\partial u}{\partial y} \end{aligned} \right\} \textcircled{1}$$

$$\frac{d\alpha}{dt} = \lim_{\Delta t \rightarrow 0} \frac{\Delta \alpha}{\Delta t} = \lim_{\Delta t \rightarrow 0} \frac{\Delta v / \Delta x}{\Delta t} = \frac{\partial v}{\partial x}$$

$$\frac{d\beta}{dt} = \lim_{\Delta t \rightarrow 0} \frac{\Delta \beta}{\Delta t} = \lim_{\Delta t \rightarrow 0} \frac{\Delta u / \Delta y}{\Delta t} = \frac{\partial u}{\partial y}$$

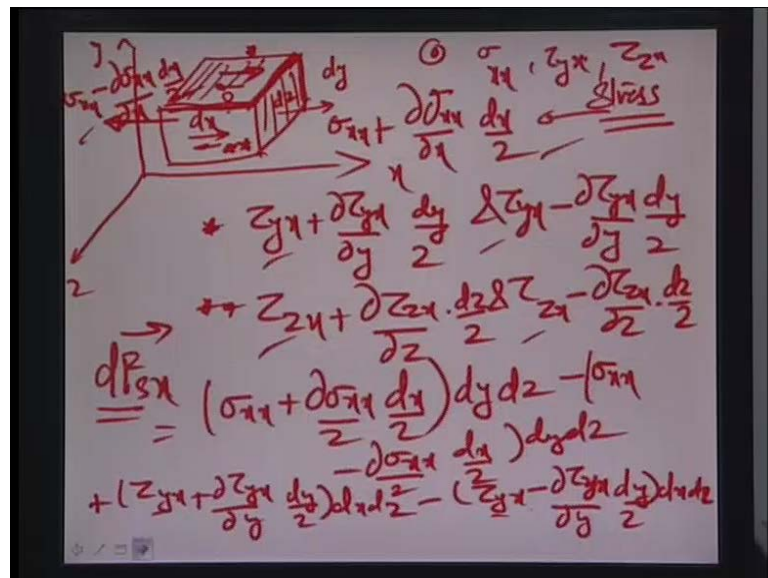

The term $\frac{\partial u}{\partial y}$ in the second equation is circled in red. At the bottom left of the whiteboard, there is a small number '9 / 33'.

Essentially, this minus $d\gamma$ by dt , which is also $d\alpha$ by dt plus $d\beta$ by dt . It would become same as Δv by Δx plus Δu by Δy . You may retreat that $d\alpha$ by dt is nothing but limit of Δt tends to 0 $\Delta \alpha$ by Δt , limit of Δt tends to 0 Δv by Δx divided by Δt , which is Δv by Δx . $\Delta \beta$ by Δt is nothing but the limit of Δt tends to 0 $\Delta \beta$ by Δt , which is equal to the limit of Δt tends to 0 Δu by Δy by Δt . It is nothing but Δu by Δy . So, this $d\beta$ by dt is positive because if you look at the deformation, it is in the same direction as the u . So, u was u_0 here and it is u_0 plus Δu by Δy times of Δy . It is in the same direction as u . Therefore, it is a positive addition and thus the relationship one holds valid. It is minus $d\gamma$ by dt and it is Δv by Δx plus Δu by Δy .

We have now found out relationships of what would happen in case of fluid element rotating by itself and a fluid element deforming by itself. With all this knowledge in mind and also the way we did the acceleration of a point vector in a fluid space, we combine all these things together to find out what dynamically alters the cube as it moves along in flow field. There would be stresses: there would be principle stresses, there would be shear stresses, which take place. Some of them we had illustrated in our last class, when we were talking about the conservation of mass equation. You will have σ_{xx} , τ_{yx} , τ_{zx} as the three stress components because of the force in the x direction. Similarly, three stress components force on the y and z directions.

We had a stress matrix or a stress tensor that we have defined in this manner. Let us see that if all these things are individually implemented. We can somehow find out the force by multiplying it with the area element of the different stresses. We can equate that to the mass of this cube into acceleration and find out what is the equation, which is emerging from that. So, this is essentially the conservation of momentum that is the Newton's second law - rate of change of momentum is nothing but the force that takes place in the direction of the force. So, applying Newton's second law here, try to see what the final states of these relationships between the different stresses like shear, principal stress and so on; **the acceleration, the mass and the area elements.**

(Refer Slide Time: 40:22)

Let us look at our cube and the control volume again. You have a small cube, which is of volume dx. So, this is x, y, z direction and dx is the distance of this particular dimension of the cube, dz is the distance of this particular dimension of the cube and dy is distance of this particular dimension of the cube. You have different forces, which are acting in the x direction. **Let us say you have a force let us just for the time being delete these arrows in the interest of space. So, we delete this we by and large know what these d x d y d z are so here we try to again do stress components we have this component of stress** We assume that this cube is centered about a point o, where you have sigma xx, tau yx, which means the area vector is in the y direction and tau zx.

At this particular edge of the cube or this particular phase, your stress components would differ. This would be σ_{xx} and let us say we have a variation in the x direction. So, $\sigma_{xx} + \frac{\partial \sigma_{xx}}{\partial x} dx$ would be the stress component in this phase. The stress component similarly in the other phase would be $\sigma_{xx} - \frac{\partial \sigma_{xx}}{\partial x} dx$. Similarly, the shear stress components would be in the opposite direction. In the lower phase, put this is a star and it would be $\tau_{yx} + \frac{\partial \tau_{yx}}{\partial y} dy$ and $\tau_{yx} - \frac{\partial \tau_{yx}}{\partial y} dy$.

Similarly, we will have the z components, which are essentially in this phase. In the backside, these components would be there. So, these double stars tell that $\tau_{zx} + \frac{\partial \tau_{zx}}{\partial z} dz$ and $\tau_{zx} - \frac{\partial \tau_{zx}}{\partial z} dz$. Therefore, dF_x , which is essentially the total amount of force in the x direction. These are the result of all different components like component 1, 2, 3, 4 and 5 6 all put together and these are all stressed terms.

So, you need a certain area of cross-section, across which these stresses are applied in order to find out the net force on the particular cube of interest. So, the net force in this case would be equal to $\sigma_{xx} + \frac{\partial \sigma_{xx}}{\partial x} dx$ times of $dy dz$. The area vector here is $dy dz$ that is dy times of dz . As I have pointed out, you have a stress in the opposite direction, which is same as σ_{xx} . Of course, minus $\frac{\partial \sigma_{xx}}{\partial x} dx$ times of $dy dz$. Similarly, you have components related to the shear and I will just try to illustrate this here as $\tau_{yx} + \frac{\partial \tau_{yx}}{\partial y} dy$ times of $dx dz$ minus $\tau_{yx} - \frac{\partial \tau_{yx}}{\partial y} dy$ times of $dx dz$. So, these are the various components in the x direction and this τ_{yx} again has a cross-sectional area dx times of dz .

(Refer Slide Time: 45:55)

$$\begin{aligned}
 & \left(\tau_{zy} + \frac{\partial \tau_{zy}}{\partial z} \frac{dz}{2} \right) dx dy \\
 & - \left(\tau_{zy} - \frac{\partial \tau_{zy}}{\partial z} \cdot \frac{dz}{2} \right) dx dy
 \end{aligned}$$

You also have a third component as a part of the whole deal. This tau zx plus delta zx by delta z times of dz by 2 times of dx dy minus tau zx minus delta tau zx by delta z plus dz by 2 into dz by 2 times of dx dy, which is the cross-sectional area.

(Refer Slide Time: 46:35)

$$\begin{aligned}
 & \sigma_{xx} + \frac{\partial \sigma_{xx}}{\partial x} \frac{dx}{2} \\
 & * \left(\tau_{yx} + \frac{\partial \tau_{yx}}{\partial y} \frac{dy}{2} \right) dz \\
 & + \left(\tau_{yx} - \frac{\partial \tau_{yx}}{\partial y} \frac{dy}{2} \right) dz \\
 & + \left(\tau_{zx} + \frac{\partial \tau_{zx}}{\partial z} \frac{dz}{2} \right) dy \\
 & - \left(\tau_{zx} - \frac{\partial \tau_{zx}}{\partial z} \frac{dz}{2} \right) dy \\
 \underline{\underline{dF_{sx}}} & = \left(\sigma_{xx} + \frac{\partial \sigma_{xx}}{\partial x} \frac{dx}{2} \right) dy dz - \sigma_{xx} dy dz \\
 & + \left(\frac{\partial \tau_{yx}}{\partial y} \frac{dy}{2} \right) dy dz - \left(\frac{\partial \tau_{yx}}{\partial y} \frac{dy}{2} \right) dy dz
 \end{aligned}$$

If I take a simplified form of all these from this expression, you can easily find out that the sigma x is actually cancelled because dy dz are similar. Similarly, the same goes true for the tau xy's. Only the differential components are retained.

Handwritten mathematical derivation on a whiteboard showing the simplification of force components in the x-direction. The derivation starts with two terms: $f(z_{x1} + \frac{\tau_{zy}}{\Delta z}) \Delta x \Delta y \Delta z$ and $-(\tau_{zy} - \frac{\tau_{zy}}{\Delta z} \cdot \frac{\Delta z}{2}) \Delta x \Delta y \Delta z$. It then shows the simplification process, resulting in $dF_{sx} = (\frac{\partial \sigma_{xx}}{\partial x} + \frac{\partial \tau_{yx}}{\partial y} + \frac{\partial \tau_{zx}}{\partial z}) \Delta x \Delta y \Delta z$. Similar expressions are shown for the y and z directions.

Similarly, here tau zx and minus tau zx are cancelled. If you assemble together all these different terms, then on simplifying, we obtain dF sx. It is nothing but delta sigma xx by delta x plus delta tau yx by delta y plus delta tau zx by delta z times of dx dy dz as the total amount of the force in the x direction. Therefore, on a more simpler note, similar kind of expressions can be generated for the different force components in the y and the z direction. Let us just write this down here and so in the y direction, it should be sigma yy times of delta y plus delta times of tau xy by delta x plus delta times of tau xz by delta z times of again dy dx dz. Similarly, you have the other component like a stress matrix, so, this comes here and this actually goes here.

In the other component, you have the delta sigma zz with respect to delta z. You have the component delta tau... Now, you have the y components and this is actually zy. You have delta tau yz by delta y plus delta tau. It is xz by delta x times of dx dy dz as a three different components of the force. If we involve the body force at this stage, to figure out how overall it would look like. We will have this equation slightly modified because we will then have to add the body forces along the x direction, the y direction. Let us call dF Bx, dF By and dF Bz as the different forces.

Therefore, if we have all these different forces together, we can say that this is actually the body force f B. It can be represented as the rho times of the volume, which is dx dy

dz times of g. It has three components: gx, gy and gz. So, let us write all these equations together in the next page.

(Refer Slide Time: 50:11)

Handwritten equations on a whiteboard:

$$d\vec{F}_x = d\vec{F}_{Bx} + d\vec{F}_{sx} = (\rho g_x + \frac{\partial \tau_{yx}}{\partial y} + \frac{\partial \tau_{zx}}{\partial z}) dx dy dz$$

$$d\vec{F}_y = d\vec{F}_{By} + d\vec{F}_{sy} = (\rho g_y + \frac{\partial \tau_{xy}}{\partial x} + \frac{\partial \tau_{zy}}{\partial z}) dx dy dz$$

$$d\vec{F}_z = d\vec{F}_{Bz} + d\vec{F}_{sz} = (\rho g_z + \frac{\partial \tau_{xz}}{\partial x} + \frac{\partial \tau_{yz}}{\partial y} + \frac{\partial \sigma_{zz}}{\partial z}) dx dy dz$$

↑ Total forces that a CV would encounter in 3-D.

The total force is in the x direction because of the body force f_{Bx} and the stress force. The force due to the stress vectors can be represented as ρg_x plus $\Delta \sigma_{xx}$ by Δx plus $\Delta \tau_{yx}$ by Δy plus τ_{zx} by Δz times of $dx dy dz$. Similarly, dF_y is again having a body force in the y direction plus a stress force in the y direction, which can be ρg_y plus $\Delta \tau_{xy}$ with respect to x plus $\Delta \sigma_{yy}$ with respect to y plus $\Delta \tau_{zy}$ with respect to z times of $dx dy dz$. Then dF_z is equal to Δ body force in the z direction, the stress force in the z direction. It is ρg_z plus $\Delta \tau_{xz}$ by Δx plus τ_{yz} by Δy plus $\Delta \sigma_{zz}$ because it is not a shear for this principle stress σ_{zz} by Δz times of $dx dy dz$.

So, these are the equations for the total forces that control volumes cv would encounter due to stresses and as well as its own weight in all the three directions. So, this brings us to the end of this particular lecture. In the next lecture, what I would like to illustrate is that we will move ahead with this force equation and try to compare it with mass times of acceleration and see what the final form of equation would look like. Thank you.
