Lecture - 13

Hello and welcome to CAD series of video lectures. This is lecture 13 on Differential Geometry curves. The layout they are in the second column here. Why? Do we need to study differential geometry or differential properties of curves. Well as I mentioned in the previous lecture. We are going to be fading segments of smaller degree through sub groups of these design points.

(Refer Slide Time: 00:47)

For example, here we have interpolated this point using a cubic polynomial. We have a second sub group again of four zero points, and we had used different cubic segment for interpolation; this is the junction point, which would be critical in curve design. Here you would need to ensure position continuity; continuity of slope and curvature. You would be matching zero order, first order and second order implement; it is these points in particular, that would motivators to study differential geometry curves.

(Refer Slide Time: 01:57)

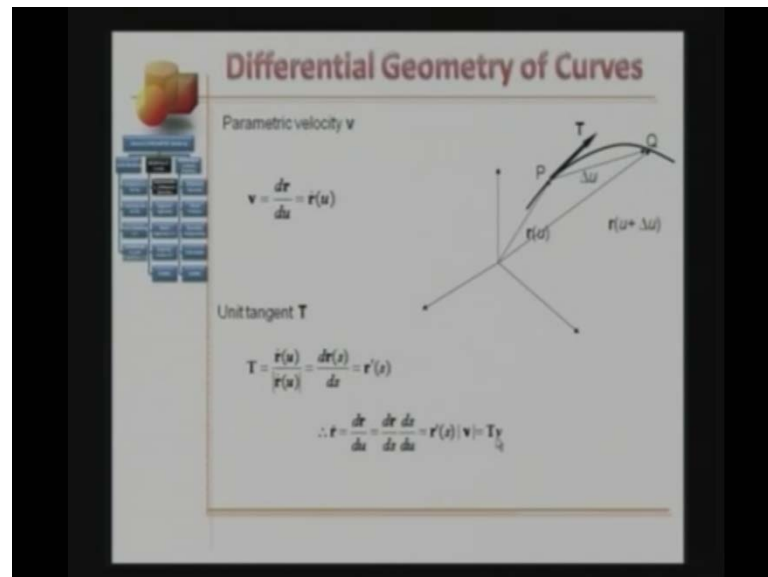

Now let us draw the Cartesian space, let us draw curve space. It is to be point P on the curve another point Q on same curve, the position vector P is $r(u)$; remember you choose to work with parametric representation, and the position vector Q is $r(u + \Delta u)$, this vector here is the different vector Δr . This bold of here represents the tangent at point P is curve, the tangent is expressed the capital teen bold.

We can use the Taylor series expansion and express position vector Q, which is $r(u + \Delta u)$ as $r(u) + \frac{dr}{du}\Delta u + \frac{1}{2}\frac{d^2r}{du^2}(\Delta u)^2$ plus they would be higher order terms. For small Δu Δr represent the arc length Δs , so Δs is approximately equal to the absolute value $|\Delta r|$, which is $|\frac{dr}{du}\Delta u|$. Here we have ignore the higher order terms; it Q approaches point P and Δs is the differential form ds , which is equal to modules of $\frac{dr}{du}du$; this derives of r with respect u is noted by \dot{r} ds is the absolute value of \dot{r} times du and mode of the \dot{r} can be written as $|\dot{r}|$ with $|\dot{r}|$ the root that time du .

Now if we wish compute total arc length from let us say point P at which the parameter value is u_0 , 2 of point Q at which the parameter value say u , then the total arc length is given by set u which is equal to integration from u_0 of $|\dot{r}|du = \int_{u_0}^u \sqrt{x'^2 + y'^2 + z'^2}du$ and if r is expressed in terms of skill of

functions, x of u , y of u , two of u and r dot will be x dot u times ψ plus y dot u times j plus t dot u times k r dot dotted with r dot is given by x dot square plus y dot square plus t dot square within radical sign du , so this integration and computed to get overall arc length.

(Refer Slide Time: 06:35)

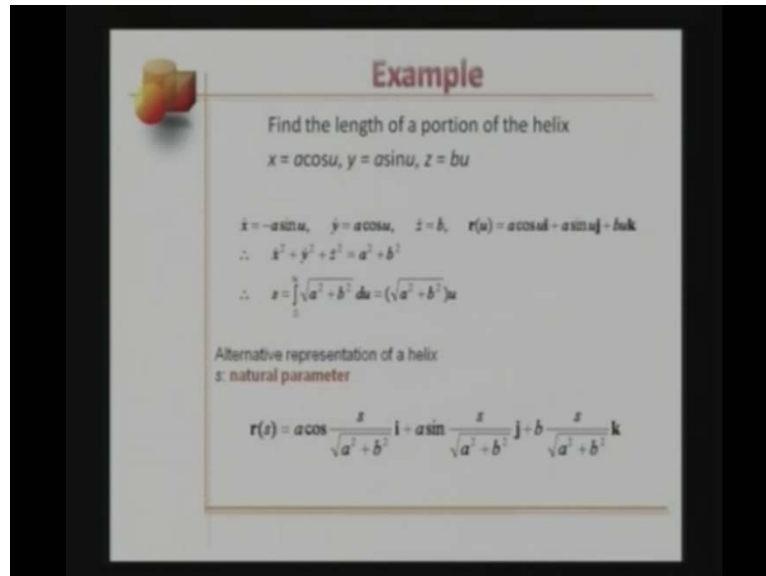

Continuing further parametric velocity bold V , is given by the first derivative r the respective u or r dot u . The unit tangent T is along the direction of the parametric velocity to v , the capital T bold is given by r dot u over the absolute value of x , which is equal to $d r$ over $d x$ now the first derivative of r with respect to x is represented by r point s , s as you seen before is be arc length parameter or the natural parameter.

First how? To be get from here to here; let me explain this to you on board. You have seen that unit tangent, t equals vector r dot u over the absolute value of same vector, which is equal to $d r$ over $d u$ over the absolute value $d r$ over $d u$. You seen from before, that $d s$ is equal to $d r$ over $d u$ the absolute value times $d u$; we plug in for this value here, we will get $d r$ vector over $d u$ here will have $d s$ here will have $d u$, u will cancel, this would be $d r$ over $d s$, which is r prime s . Recall that we are using dot rotation to represent derivative with respect to u and using the prime rotation represent derivative with respect to x ; now r dot is equal to $d r$ over $d u$ by change row this is equal to $d r$ over $d s$ prime $d s$ over $d u$, $d r$ over $d s$ is over prime as $d s$ over $d u$ is the absolute value

of the parametric velocity or from s is the unit tangent T times the magnitude of the parametric velocity.

(Refer Slide Time: 10:14)

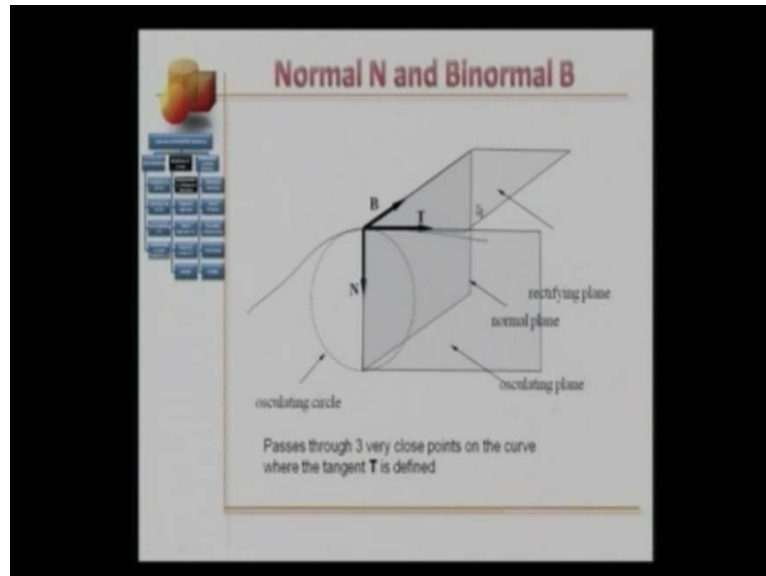

Take an example, find the length of a portion of the helix given by x equals $a \cos$ of u , y equals $a \sin$ of u and z equals b times u , a is the radius of the helix, b is related in the pitch and u is the parameter. All unit to do that is compute x dot derivative of x with respect to u , derivative of y with respect to u and derivative of z with respect to u , x dot equals minus $a \sin$ of u , y dot equals to $a \cos$ of u , z dot equals b . Note in the parametric form of \mathbf{r} u is $a \cos$ of u and \mathbf{i} plus $a \sin$ of u and \mathbf{j} plus $b u$ and \mathbf{k} ; x dot squared plus y dot squared plus z dot squared can be determined to be $a^2 + b^2$. You seen for how to compute the arc length; s equal here we taken u sub 0 as 0 , integration from 0 to u under root x dot squared plus y dot squared plus z dot squared, which is under root $a^2 + b^2$ times du and clearly the integration consist to be $a^2 + b^2$ with in the numeric sign times u .

What we observed here is an alternative, which to represent a helix using a different parameter; s note that this equation relates s with u for this helix. All within do is substitute for u and write this expression in terms of s , as $a \cos$ s over under root $a^2 + b^2$ times plus $a \sin$ s over under root $a^2 + b^2$ and \mathbf{j} plus b hence s over under root $a^2 + b^2$ times \mathbf{k} ; this expression and this expression there all u . The defense on a convenience whether we would want to choose

do work with parameter u or parameter s compute different differential properties of the curve.

(Refer Slide Time: 13:40)

The Normal and Binormal and point in the curve. Normal is given by N and Binormal is B ; Well we have this curve, we have this unit tangent T and we have a plane which is perpendicular to this unit tangent, are sum point p ; this plane will disband by two vectors both are which will be orthogonal each other and also orthogonal to the unit tangent t . This is the first one represented by N and this is second one represented by B . N is called the normal and B is called binormal.

The plane containing two normal N and B this called normal plane; the plane containing the unit tangent and the binormal is called the rectifying plane. And the plane stand by N and T called as the osculating plane. If you considered two points very very close to this point; as we know, a circle can pass through three points we can construct a circle that passes through this points; the circle is called osculating circle. Notice well the normal points towards the centre circle, as said earlier this osculating circle passes through three very close points in the curve where the tangent T is defined.

(Refer Slide Time: 16:09)

Normal N and Binormal B ...

Normal **N**

$T(s) = \frac{dr(s)}{ds} = r'(s)$ and $T(s + \Delta s) = r'(s + \Delta s)$

Change in direction of **T**

$n = \Delta T(s) = T(s + \Delta s) - T(s) = \left\{ T(s) + \frac{dT}{ds} \Delta s + \dots \right\} - T(s)$

$n = \frac{dT(s)}{ds} \Delta s$

Now $r'(s) \cdot r'(s) = 1$ $r' \cdot r' = r'' \cdot r' = 0 \Rightarrow 2r' \cdot r'' = 0 \Rightarrow r' \cdot r'' = 0$

r' or **T** and **r''** are orthogonal to each other. DEFINE **N** such that κ is a scalar **N** is a unit vector

$\kappa N = \frac{dT}{ds}$

Binormal **B** = **T** × **N**

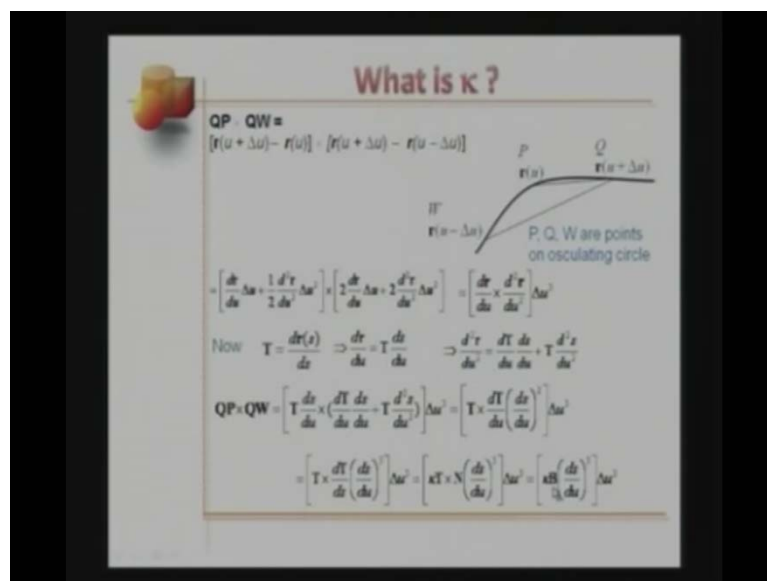

Some more on the normal and binormal, normal N how to compute that? There we have T which is evaluated as $\frac{dr}{ds}$, in short represented by r' at a point very close to this point will have T of $s + \Delta s$ which can be computed as r' at $s + \Delta s$. Let us see how the direction of the unit tangent changes, we have this curve we have T s. Here the unit tangent at some point and then arc a point very close to this point, we have another unit tangent T of $s + \Delta s$. What we do? We move T s to that the steps to these tangents rejoin this vector here represents the difference vector, n equals T s plus delta s minus T s. Notice that this is T s for n is delta T of s which is T of $s + \Delta s$ minus T s, we can use the Taylor series expansion this expand this expression.

Here $s + \Delta s$ T over Δs time's Δs plus some higher order terms minus T s, these two will cancel all and we ignore the higher order terms delta T s will be approximated by $\frac{dT}{ds} \Delta s$. For two points very, very close to each other, delta T over delta s will take the differential form $\frac{dT}{ds}$ which will be given by r'' . Remember that we are using the prime rotation to represent derivatives to respect to the natural of the arc length parameter. Now we know that t is the unit tangent and so its magnitude is 1 in a sense $r' \cdot r' = 1$.

If we differentiate this equation to respect to s, we get $r' \cdot r'' + r' \cdot r'' = 0$ which implies eventually. That $r' \cdot r'' = 0$

dotted with r double prime is equal to 0, what would this mean basically? This would mean that r double prime is a vector which is orthogonal to r prime, r prime is a unit tangent T . In other words r double prime will be orthogonal to the unit tangent T . We can use this fact and define normal N such that, some scalar κ time's N equal r double prime which is d^2T over dx . κ is a scalar use so that n happen to be a unit vector, here κ is a scalar and N is a unit vector. Finally, the binormal B is given by the cross product between the unit tangent and the unit normal. We know that both T and N are orthogonal to each other; it is the scalar κ that we need to investigate. (())

(Refer Slide time: 21:22)

Question; what is kappa? Does it have any physical elements or significance, we have a curve here this point is P with position vector r of u , this point here Q with position vector r of u plus Δu . This is point W with position vector r of u minus Δu , now P, Q and W are points very close to each other, we can say they all lie on the parameter of the osculating circle. Now let us compute QP cross with QW, QP cross with QW; QP is given by r of u plus Δu minus r of u and QW is given by r of u plus Δu minus r of u and minus Δu . We use the Taylor series expansion and considered terms up to second derivatives, r of u plus Δu will be r of u plus $\frac{dr}{du}$ times Δu plus half of $\frac{d^2r}{du^2}$ times Δu square; the term r of u will cancel with this. So these two terms are what which you left and r of u plus Δu minus r of u minus Δu then both expanded using Taylor series will gave us 2 times $\frac{dr}{du}$ times Δu plus 2 times $\frac{d^2r}{du^2}$ times Δu square.

Let us try to simplify this cross product further; well what happens with this term gets cross with this term? Note that the direction $\frac{dr}{ds}$ over $\frac{du}{ds}$ is the same in both terms, so the corresponding cross product will be 0. Next this term crossing with this term, will have 2 times $\frac{dr}{ds}$ over $\frac{du}{ds}$ cross with $\frac{d^2r}{ds^2}$ over $\frac{du}{ds}$ square times Δu cube. Now this term crossing with this term, this half cancels to this 2; will have $\frac{d^2r}{ds^2}$ over $\frac{du}{ds}$ square cross with $\frac{dr}{ds}$ over $\frac{du}{ds}$. If a reverse the two terms along the cross product, I will introduce a negative sign. If we further work out the algebra, this cross product will reduce to $\frac{dr}{ds}$ over $\frac{du}{ds}$ cross with $\frac{d^2r}{ds^2}$ over $\frac{du}{ds}$ square times Δu cube.

Now we know that the unit tangent is given by $\frac{dr}{ds}$ which is r' , this for imply using change rule that $\frac{dr}{ds}$ over $\frac{du}{ds}$ is equal to T the unit tangent times $\frac{ds}{du}$. All I need to do is multiply and divide the expression by $\frac{du}{ds}$ and rearrange this equation to get this result. Now if I compute the second derivative of r respect to u that is if I differentiate this expression again with respect u , I get the $\frac{d^2r}{ds^2}$ over $\frac{du}{ds}$ square which is equal to $\frac{dT}{ds}$ over $\frac{du}{ds}$ time $\frac{ds}{du}$ plus T times $\frac{d^2s}{ds^2}$ over $\frac{du}{ds}$ square.

All I can do now is, replace this term here by this term on the right hand side of this equation. Therefore, $Q \cdot P$ plus $Q \cdot W$ is given by T times $\frac{ds}{du}$; notice that I am replacing $\frac{dr}{ds}$ over $\frac{du}{ds}$ as well by this expression. So T times $\frac{ds}{du}$ cross with $\frac{dT}{ds}$ over $\frac{du}{ds}$ times $\frac{ds}{du}$ plus T times $\frac{d^2s}{ds^2}$ over $\frac{du}{ds}$ square, this entire things time's Δu . If I work on this cross product further and notices that the direction of this term and this term the two directions are the same, so the corresponding cross product is 0. So all is left is, T cross with $\frac{dT}{ds}$ over $\frac{du}{ds}$ which is this term and this term times $\frac{ds}{du}$ whole square these two terms getting multiply times Δu cube.

Now let us see how this term can we written in terms of the other normal N and B ; the normal and binormal, well as you see you retain this scalar $\frac{dx}{ds}$ over $\frac{du}{ds}$ here. We know from before that $\frac{dT}{ds}$ is κ times N to we see this two terms here, κN and we retain this term T here. So this expression becomes κ times T cross with N times this scalar $\frac{ds}{du}$ whole cube times Δu cube and T cross N is binormal B . In other words $Q \cdot P$ cross with $Q \cdot W$, now this κ times the binormal vector B times the scalar $\frac{ds}{du}$ the whole cube times Δu cube. Let us retain this result that can be using this in the next slide.

(Refer Slide Time: 30:17)

What is κ ? ...

Radius of curvature

$$\rho = \frac{|WP| |WQ| |WP - WQ|}{2 |PQ \times WQ|}$$

$$\rho = \frac{|\Delta u \frac{dr}{du} + \frac{1}{2} \frac{d^2r}{du^2} \Delta u^2 + \dots| |2\Delta u \frac{dr}{du} + \dots| |\Delta u \frac{dr}{du} + \frac{1}{2} \frac{d^2r}{du^2} \Delta u^2 + \dots|}{2 \left| \frac{dr}{du} \times \frac{d^2r}{du^2} \right| \Delta u^3}$$

$$= \frac{|\Delta u| \left| \frac{dr}{du} \right|}{\left| \frac{dr}{du} \times \frac{d^2r}{du^2} \right| \Delta u^3}$$

From previous result

$$\rho = \frac{\left| \frac{dr}{du} \right|}{\left| \frac{dr}{du} \times \frac{d^2r}{du^2} \right|} = \frac{1}{\kappa \left| \frac{dr}{du} \right|^2} = \frac{1}{\kappa}$$

κ , called curvature, is the inverse of the radius of curvature

Back to this figure here, we have curve and points P Q and W; where position vector $r(u)$, $r(u + \Delta u)$ and $r(u - \Delta u)$. Using vector algebra radius curvature is given by ρ which is equal to modulus vector W P times modulus of vector W Q times modulus vector W P minus W Q, W P minus W Q over two times modulus on the cross product between the vector P Q and W Q. Well we can compute this vector in terms of the corresponding position vectors.

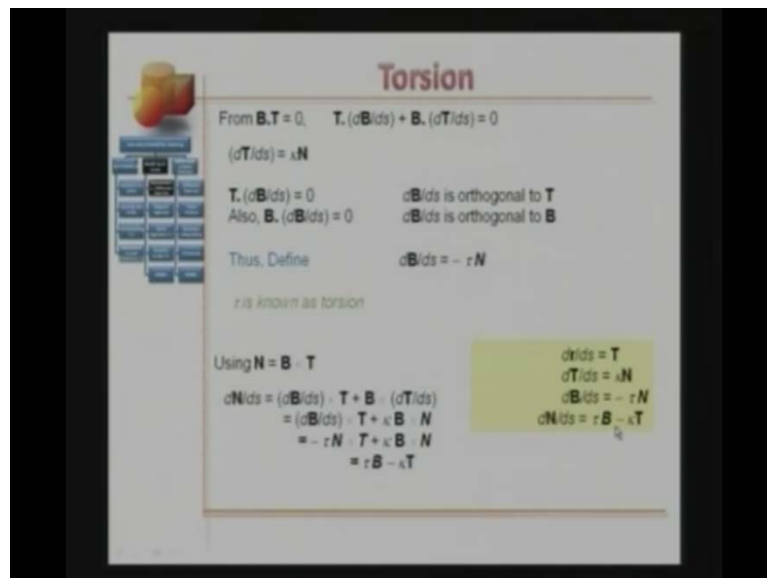

This looks a little tedious, this factor work it out; ρ equals the mark W P, which is Δu times $\frac{dr}{du}$ over Δu minus half $\frac{d^2r}{du^2}$ times Δu^2 plus some high order terms. Mod of W P which is $2 \Delta u$ times $\frac{dr}{du}$ plus again some higher returns. Mod of vectors W P minus W Q which is Δu hence $\frac{dr}{du}$ plus half of $\frac{d^2r}{du^2}$ times Δu^2 plus some higher returns. These expressions can be obtain using Taylor series expansion with some additional algebra, we denominated given by $2 \Delta u$ times $\frac{dr}{du}$ cross with $\frac{d^2r}{du^2}$ the mortals that times Δu^3 . You may want to work as an exercise, as to have the radius curvature is computed using this expression.

Now starting with this complicated looking expression, ρ can be simplified to be Δu^3 times $\frac{dr}{du}$, the absolute value the cube that over $\frac{dr}{du}$ cross with $\frac{d^2r}{du^2}$ over Δu^3 the absolute value this times Δu^3 . We see from this expression

that Δu cube can get cancel now and ρ becomes modulus $\frac{dr}{du}$ the whole cube over modulus of the cross product it mean $\frac{dr}{du}$ and $\frac{d^2r}{du^2}$.

From the result in the previous slide, we can replace this expression and rewrite this equation as $\rho = \frac{1}{\kappa} \frac{dr}{du}$ the whole cube over $\frac{ds}{du}$ the whole cube. And noting that $\frac{dr}{du}$ is the same as $\frac{ds}{du}$, the 2 terms gets cancel the ρ is equal to $\frac{1}{\kappa}$. The κ after roll has some physical significance it is called curvature and it is inverse radius curvature ρ .

(Refer Slide Time: 35:28)

Next torsion, another differential property of curves; we know that the binormal \mathbf{b} and tangent \mathbf{t} orthogonal. So, $\mathbf{b} \cdot \mathbf{t} = 0$. What we can do is, we can differentiate this result with respect to s as to get $\mathbf{T} \cdot \frac{d\mathbf{B}}{ds} + \mathbf{B} \cdot \frac{d\mathbf{T}}{ds}$, right hand side is going to be 0. And we can use the definition, $\frac{d\mathbf{T}}{ds} = \kappa \mathbf{N}$; and substitute this expression here. For defined, when we substitute this thing here is that $\mathbf{B} \cdot \frac{d\mathbf{N}}{ds}$ will be 0, which would make $\mathbf{T} \cdot \frac{d\mathbf{B}}{ds} = 0$; at here $\mathbf{T} \cdot \frac{d\mathbf{B}}{ds} = 0$, which physically implies that the first derivative of binormal with respect to the arc length is orthogonal to \mathbf{T} .

Also if we differentiate these are \mathbf{B} respective s , we will see that $\mathbf{B} \cdot \frac{d\mathbf{B}}{ds} = 0$; implying that $\frac{d\mathbf{B}}{ds}$ is orthogonal to \mathbf{B} . Interesting, $\frac{d\mathbf{B}}{ds}$ is orthogonal to \mathbf{T} and also $\frac{d\mathbf{B}}{ds}$ is perpendicular to $\mathbf{B} \cdot \frac{d\mathbf{B}}{ds}$. Therefore, is

bound to be aligned with the unit normal N , we can use this fact to define $\frac{dB}{ds}$ as $-\tau N$, this scalar τ is known as torsion. Using the fact that the unit normal N is expressed as the cross product between the binormal and the unit tangent. We can write $\frac{dN}{ds}$ as $\frac{dB}{ds} \times T + B \times \frac{dT}{ds}$. Following the algebra further, the right hand side here can be written as $\frac{dB}{ds} \times T + \kappa B \times N$. So this time here the $\kappa B \times N$ term here can be replaced by $-\tau N \times T + \kappa B \times N$, $N \times T = B$ and $B \times N = -T$. So, $\frac{dN}{ds} = \tau B - \kappa T$.

In summary, we get four relations; number one $\frac{dr}{ds}$ is defined as unit tangent T . $\frac{dT}{ds}$ is defined as scalar κ which we have seen to be inverse of radius of curvature, times the unit normal N . $\frac{dB}{ds}$ is defined as $-\tau N$ the scalar τ is called the torsion. And $\frac{dN}{ds}$ is $\tau B - \kappa T$. If you see the left hand side of these relations r , T , B and N ; the left hand sides express the first derivatives with respect to s , and the right side respectively express the corresponding results. These four relations are known as Frenet-Serret Formulae. In subsequent lectures, we are going to be using these relations to compute the differential properties of curves at different points.
