Methods of Linear ODE's

Good morning, as we saw in the last lecture the method of undetermined coefficients for solving the linear non homogeneous ODEs is limited by the necessity of constant coefficient and it can handle only if you selected functions as the right hand side. Namely, the polynomials, exponential function, sinusoids and their combinations.

(Refer Slide Time: 00:29)

Now, for general situations in which the right hand side function can be anything the input function can be anything, and the coefficients are also not required to be constant if they are functions if they are variable coefficients, then the general method for solving the non homogeneous differential equation is the method of variation of parameter.

(Refer Slide Time: 01:14)

Mathematical Methods in Engineering and Science Second Order Linear Non-Homogeneous ODE's 1997

Linear ODE's and Their Solutions

Method of Variation of Parameters
Close

Method of Variation of Parameters

Solution of the HE:

$$y_h(x) = c_1 y_1(x) + c_2 y_2(x),$$

in which c_1 and c_2 are constant 'parameters'.

For solution of the NHE,
how about 'variable parameters'?

Propose

$$y_p(x) = u_1(x)y_1(x) + u_2(x)y_2(x)$$

and force $y_p(x)$ to satisfy the ODE.

A single *second order ODE* in $u_1(x)$ and $u_2(x)$.
We need one more condition to fix them.

In this we first note that if y_1 and y_2 are 2 linearly independent solutions of the corresponding homogeneous equations, then this combination this linear combination with constant parameters c_1 and c_2 gives as the general solution of the homogeneous equation that is the complimentary function for the purpose of the non-homogeneous equation. Now, for the non-homogeneous equation the solution needs to be linearly independent of these two basis members. Now as long as these parameters are constant we cannot have linearly independent function.

So, what we try to think is that how about making these parameters as variables, that is as functions of x and as we do that and we replace c_1 and c_2 by 2 functions u_1 of x and u_2 of x then what we are doing we are conducting a variation of parameters and that is why this method is called variation of parameters. So, we consider variable parameters. So, we propose the particular solution of the non homogeneous ordinary differential equation as $u_1 y_1$ plus $u_2 y_2$, and then we asked for the functions u_1 and u_2 that will make this y_p satisfy the given differential equation.

Now, one point is very clear that we can take this y_p and force it to satisfy the differential equation, that will mean that we will differentiate it twice and then take this y_p and the resulting y_p' and y_p'' and insert in that equation and we will say that this equation is now satisfied. But that we will give us a single second order ODE in u_1 and u_2 . Now there are 2 unknown functions to be determined and for that a single

differential equation is not enough; we will need two differential equations to solve for two unknown function. So, one more condition is needed to fix them.

Now, at this stage we need one more condition between u_1 and u_2 , apart from the condition that together they have to make y_p satisfy the differential equation apart from that we need one more condition and we try to frame that additional condition in such a manner that our work is also reduced our work is also made more easy the way to do that

Method of Variation of Parameters

From $y_p = u_1 y_1 + u_2 y_2$,

$$y_p' = u_1' y_1 + u_1 y_1' + u_2' y_2 + u_2 y_2'$$

Condition $u_1' y_1 + u_2' y_2 = 0$ gives

$$y_p' = u_1 y_1' + u_2 y_2'$$

Differentiating,

$$y_p'' = u_1' y_1' + u_2' y_2' + u_1 y_1'' + u_2 y_2''$$

Substitution into the ODE:

$$u_1' y_1' + u_2' y_2' + u_1 y_1'' + u_2 y_2'' + P(x)(u_1 y_1' + u_2 y_2') + Q(x)(u_1 y_1 + u_2 y_2) = R(x)$$

Rearranging,

$$u_1' y_1' + u_2' y_2' + u_1 (y_1'' + P(x)y_1' + Q(x)y_1) + u_2 (y_2'' + P(x)y_2' + Q(x)y_2) = R(x)$$

As y_1 and y_2 satisfy the associated HE, $u_1' y_1' + u_2' y_2' = R(x)$

is at first as we differentiate y_p this function this proposed function, we get $u_1' y_1 + u_1 y_1' + u_2' y_2 + u_2 y_2'$. So, these are the four terms in the derivative of these 2 terms here.

Now, we know that as we differentiate it further, then u_1, u_2, y_1, y_2 all four of them will generate their second derivatives; and that means, that the resulting expression for y_p double prime will have up to second derivatives of all the four functions y_1, y_2, u_1, u_2 . With y_1 and y_2 there is no difficulty because they are known functions. But u_1 and u_2 when they are when involved their second derivatives that mean that the resulting differential equation will be a second order differential equation. The additional condition that we need we can choose in a particular manner which will obviate that second order.

So, what we do is that from here we collect the terms which has the first derivatives of the unknown functions u_1 and u_2 so; that means, this term and this term and together we say that we will impose the condition on functions u_1 and u_2 that, this term and this term together vanishes that is we impose this plus this equal to 0. If we do that then y'' reduces to the sum of the rest of the 2 terms this. Now in this expression in y'' we have got the derivatives of y_1 and y_2 , but not the derivatives of the unknown functions.

So, that way when we now differentiate this, we get the derivatives of the unknown functions only up to first order. So, that is this y'' that again with the now ordinary product rule will give a $u_1' y_1' + u_1 y_1''$ and similarly 2 terms from here right. Now here again we find that the unknown functions u_1 and u_2 are involved only up to the first derivative; known functions y_1 and y_2 are involved up to second derivatives, but that is not a difficulty.

Now, on this note that another condition like this we cannot impose, because if we impose another condition like this that is if we try to say that these 2 together also vanish then there will not make sense because this condition and that condition together will imply that u_1' and u_2' are all are both 0 right because these 2 this condition and this condition together will mean that we are looking for u_1' u_2' , which satisfy a homogeneous system of linear equation is not a singular coefficient matrix. So, that we will give only the trivial 0 solution, u_1' u_2' will become 0 which means that u_1 and u_2 will turn out to be constant and that will not give us a solution of the non homogeneous equation.

So obviously, only one condition we needed and that we have got the second condition we need to get by substituting this y'' this y' and this y sorry this y'' , this y' and this y into the differential equation. As we do that y'' these 4 terms plus P into y' , plus Q into y is equal to Rx. this is the given differential equation. Now as we rearrange these terms collecting together all terms which have u_1 that is this is the first term, then from here we will get $P y_1'$ and then from here we will get $Q y_1$ right. So, we collect the u_1 terms together and u_2 terms together.

Now, we know that y_1 and y_2 are solutions of the corresponding homogeneous equation; that means, that this equal to 0 and similarly this equal to 0. So, then concerning these 2 0 terms we get $u_1' y_1' + u_2' y_2'$ as equal to Rx . Now this condition that we imposed through which we also simplified the expression of y_p' , through which we avoided the second derivatives of $u_1 u_2$ in the resulting equation here that is one equation and the given differential equation gives us the second equation in 2 unknowns the unknowns are u_1' and u_2' .

Now, this equation and this equation if we write in the proper matrix vector form, then $y_1 y_2 y_1' y_2'$ come in the coefficients and we get the system of equation in the standard form.

 Course

$$\begin{bmatrix} y_1 & y_2 \\ y_1' & y_2' \end{bmatrix} \begin{bmatrix} u_1' \\ u_2' \end{bmatrix} = \begin{bmatrix} 0 \\ R \end{bmatrix}$$

Since Wronskian is non-zero, this system has unique solution

$$u_1' = -\frac{y_2 R}{W} \quad \text{and} \quad u_2' = \frac{y_1 R}{W}$$

Direct quadrature:

$$u_1(x) = -\int \frac{y_2(x)R(x)}{W[y_1(x), y_2(x)]} dx \quad \text{and} \quad u_2(x) = \int \frac{y_1(x)R(x)}{W[y_1(x), y_2(x)]} dx$$

*In contrast to the method of undetermined multipliers, variation of parameters is **general**. It is applicable for all continuous functions as $P(x)$, $Q(x)$ and $R(x)$.*

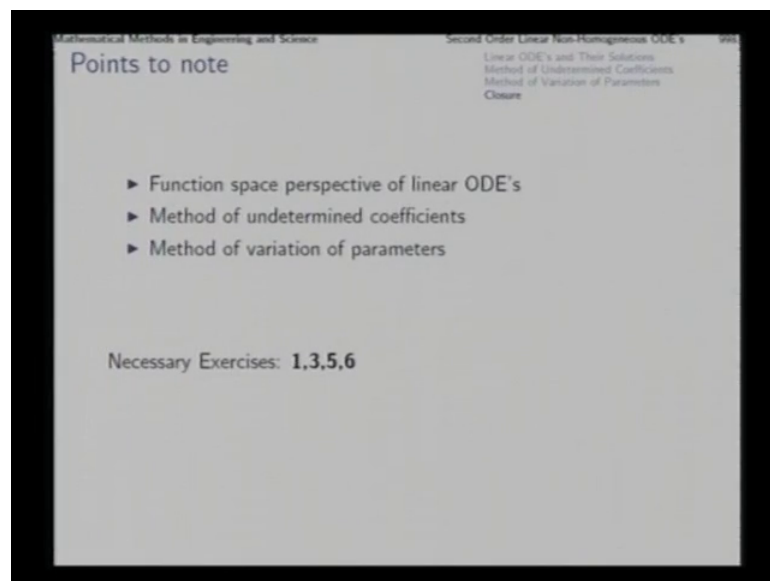

Now if we solve this then we will get u_1' and u_2' and we already know that this matrix is non singular for all values of x under question in the interval for which we are looking for the solution. Now the determinant of this matrix is actually the Wronskian. So, as long as y_1 and y_2 are linearly independent solutions forming the basis for the solutions of the homogeneous equation. So, we know that these are 2 linearly independent functions. So, this Wronskian will be non zero.

So; that means, that the solution of this we will give us unique u_1' u_2' in other words this is an invertible matrix. So, you get that solution. As we get that solution from the 2 equations here we get u_1' as this and u_2' as this, Wronskian goes

in the denominator which is not a problem because it is non zero and then this is a known function of x similarly this is another known function of x . So, direct integration will give as u_1 and u_2 these u_1 and u_2 when put in the proposed form of the particular solution will give us the particular solution that we are looking for that is $u_1 y_1 + u_2 y_2$ ok.

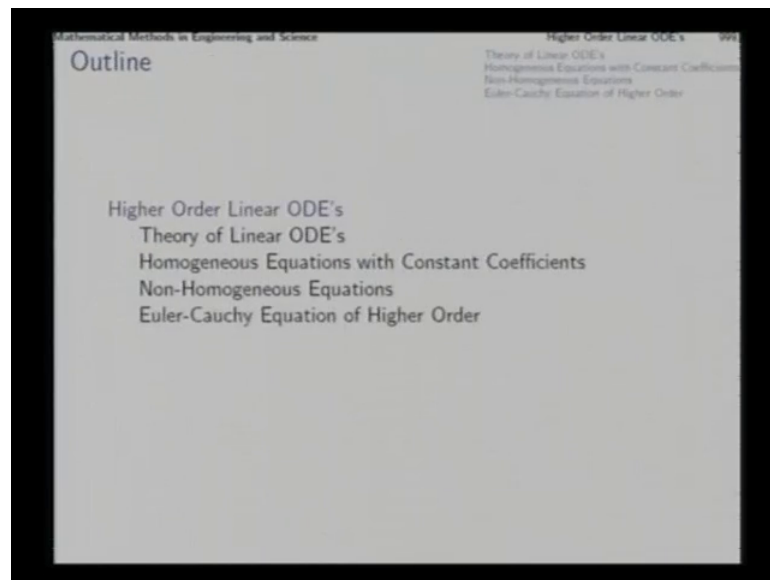

So, this is the method of variation of parameters to find the solution of the non homogeneous differential equation in a general situation, and the first step even in this is to find the solution complete solution of the corresponding homogeneous equation, that is the first step because they will form this matrix here. So, this is applicable for all functions $P(x)$, $Q(x)$ and $R(x)$ which are continuous and bounded, and it will be valid only for that interval in which these functions remain.

(Refer Slide Time: 11:20)

So, in this relation these are the important points that we have studied after looking at the function space perspective of linear ODEs we studied these 2 methods undetermined coefficients and variation of parameters. These same methods and the previous discussions on finding the solution of the corresponding homogeneous equation all these now we generalize for higher order differential equations.

(Refer Slide Time: 11:51)

(Refer Slide Time: 11:55)

First we consider this equation; this is the general linear ordinary differential equation of say n th order. So, up to the n th derivative is appearing linear and these are coefficient functions which depend on x only.

Now, understand again that we are here going to consider only those cases where P_1, P_2, P_3 up to P_n and R these are functions of x which are continuous and bounded in the interval under discussion. Now again for this will have the general solution in this manner as y_h plus y_p , where y_h is the complimentary function in other words y_h is the

general solution of the corresponding homogeneous equation that is this equal to 0 that is it is solution it is a general solution of this equation.

Now, for the homogenous equation suppose we have got n solutions, y_1, y_2, y_3 etcetera then the state vectors of these solutions when assembled as column vectors in a matrix, then what we have it is an nth order differential equation. So, state vector will have the function itself its first derivative second derivative up to n minus 1 th derivatives. So, this is the state vector of the first solution similarly this is the second vector second state vector for this corresponding to this and so on. So, when we assemble these as columns then we get an n by n matrix of functions, that is the first row is these functions second row will have its first derivatives, third row will have the second derivatives fourth row will have the third derivatives and so on the last row the nth row will have the n minus 1 th derivatives of these functions.

So, this is the fundamental matrix which will appear again and again. Now first point is what is the Wronskian in this case. So, the determinant of this matrix is the Wronskian in this case, this is a direct generalization of the case of second order differential equation. So, this is the Wronskian of all these solutions all these n solutions. Now parallel to the theory that we studied in the case of second order differential equations here we will have corresponding points.

Theory of Linear ODE's

Theory of Linear ODE's
Homogeneous Equations with Constant Coefficients
Non-Homogeneous Equations
Euler-Cauchy Equation of Higher Order

- ▶ If solutions $y_1(x), y_2(x), \dots, y_n(x)$ of HE are linearly dependent, then for a non-zero $\mathbf{k} \in \mathbb{R}^n$,

$$\sum_{i=1}^n k_i y_i(x) = 0 \Rightarrow \sum_{i=1}^n k_i y_i^{(j)}(x) = 0 \text{ for } j = 1, 2, 3, \dots, (n-1)$$

$$\Rightarrow [\mathbf{Y}(x)]\mathbf{k} = \mathbf{0} \Rightarrow [\mathbf{Y}(x)] \text{ is singular}$$

$$\Rightarrow W[y_1(x), y_2(x), \dots, y_n(x)] = 0.$$
- ▶ If Wronskian is zero at $x = x_0$, then $\mathbf{Y}(x_0)$ is singular and a non-zero $\mathbf{k} \in \text{Null}[\mathbf{Y}(x_0)]$ gives $\sum_{i=1}^n k_i y_i(x) = 0$, implying $y_1(x), y_2(x), \dots, y_n(x)$ to be linearly dependent.
- ▶ Zero Wronskian at some $x = x_0$ implies zero Wronskian everywhere. Non-zero Wronskian at some $x = x_1$ ensures non-zero Wronskian everywhere and the corresponding solutions as linearly independent.
- ▶ With n linearly independent solutions $y_1(x), y_2(x), \dots, y_n(x)$ of the HE, we have its general solution $y_h(x) = \sum_{i=1}^n c_i y_i(x)$, acting as the complementary function for the NHE.

First point is that if these n solutions of the homogeneous equation are linearly dependent then the Wronskian will be 0 how do we prove that? We say that if these are linearly dependent then for a non zero vector k we can find this that is we can have a linear combination of the n solutions 0 even though each contribution is not individually 0 that is for a set of case $k_1 k_2 k_3$ up to k_n not all 0 together, we can find a linear combination of these y is which turns out to be 0 if they are linearly dependent.

And if so, that will mean that the derivative of this will give us \sum there is some of $k_i y_i'$ as 0 as $k_i y_i'$ it is j is equal to 1. The derivative of that will give us $k_i y_i''$ equal to 0 that is for j equal to 2 and so on that means, up to $n - 1$ we can construct these sums and get them 0 if the solutions are linearly dependent. Now note that this will mean this and this together will mean that the fundamental matrix y into k is equal to 0, which means that its first row is this, second row is this for j equal to 1, third row of this matrix vector equation is this same thing for j equal to 2 and so on.

So, the complete n rows we can call step like this, and note again that if y_1 through the y_n are n linearly dependent solutions then we can construct such a matrix vector equation homogeneous equation 0 on this side and have a solution which is not zero that is vector k is not 0, and that means, that this thing coefficient matrix y must be singular because for the homogenous system of equation to have a non trivial solution k it, is necessary that the coefficient matrix is singular. So, Yx is singular which means that its determinant the Wronskian is 0. So, this is the first point that is the n solutions of the homogeneous equation being linearly dependent will imply that the Wronskian is 0.

Now, if the Wronskian now we try to show the converse; if the Wronskian is 0 at some point then y this matrix at that point evaluated at that point is singular and then that will mean that a non zero vector k can be found in its null space, which will in turn give this which will imply that the solutions are linearly dependent. So, this is the converse of this now together they also mean that 0 Wronskian at some point $x = 0$ will immediately imply 0 Wronskian everywhere because 0 Wronskian at some point will mean that the solutions are linearly dependent which in turn will mean that the Wronskian is 0 everywhere this is x and that will again mean that non zero Wronskian at some point will ensure non zero Wronskian everywhere and the corresponding solution as linearly independent.

So, now what we do with those linearly independent solutions if the Wronskian is non zero, we say that with these n linearly independent solutions of the homogenous equation we have the general solution in this manner as we had for the case of second order differential equation and this linear combination, the complete solution of the homogenous equation will serve as the complimentary function for the solution of the non homogeneous equation.

Now, we consider the first case of constant coefficients.

(Refer Slide Time: 18:49)

Mathematical Methods in Engineering and Science Higher Order Linear ODE's 2020
 Homogeneous Equations with Constant Coefficients
 Non-Homogeneous Equations Constant Coefficients
 Euler-Cauchy Equation of Higher Order

$$y^{(n)} + a_1 y^{(n-1)} + a_2 y^{(n-2)} + \dots + a_{n-1} y' + a_n y = 0$$

With trial solution $y = e^{\lambda x}$, the auxiliary equation:

$$\lambda^n + a_1 \lambda^{n-1} + a_2 \lambda^{n-2} + \dots + a_{n-1} \lambda + a_n = 0$$

Construction of the basis:

1. For every simple real root $\lambda = \gamma$, $e^{\gamma x}$ is a solution.
2. For every simple pair of complex roots $\lambda = \mu \pm i\omega$, $e^{\mu x} \cos \omega x$ and $e^{\mu x} \sin \omega x$ are linearly independent solutions.
3. For every real root $\lambda = \gamma$ of multiplicity r ; $e^{\gamma x}$, $x e^{\gamma x}$, $x^2 e^{\gamma x}$, \dots , $x^{r-1} e^{\gamma x}$ are all linearly independent solutions.
4. For every complex pair of roots $\lambda = \mu \pm i\omega$ of multiplicity r ; $e^{\mu x} \cos \omega x$, $e^{\mu x} \sin \omega x$, $x e^{\mu x} \cos \omega x$, $x e^{\mu x} \sin \omega x$, \dots , $x^{r-1} e^{\mu x} \cos \omega x$, $x^{r-1} e^{\mu x} \sin \omega x$ are the required solutions.

Consider this constant coefficient case for homogeneous equation, for which the complete solution of homogeneous equation we can find. If the coefficients are functions $p_1(x)$, $p_2(x)$ and so on then in general we are not able there are no analytical procedures to find out all the solutions of this homogenous equation. Now, in this case if the coefficient are constant, then we can do that exactly as the second order case with necessary extensions and changes. Here also the left hand side of this equation has y , y' , y'' in linear combination. So, we expect solutions of this form exponential solution.

So, if we take a trial solution of this kind and insert it its derivatives as many times we differentiate that when you lambdas get multiplied with it. So, we get the auxiliary equation as $\lambda^n + a_1 \lambda^{n-1} + a_2 \lambda^{n-2} + \dots + a_{n-1} \lambda + a_n = 0$ and so on till from here we get an. Now this is a polynomial equation of n th degree; that means, it will

have n solutions. So, out of from those n solutions for every simple real root that is if γ is one solution of this polynomial equation appearing only one, that is in its factorization if $\lambda - \gamma$ appears only one that is that makes it is a simple root.

So, then corresponding to that $e^{\gamma x}$ would be a solution. It is for every simple real root the corresponding exponential function will be a solution of this differential equation, because that is the idea with which this was started. For every pair of complex roots like this $\mu \pm i\omega$, you will say that $e^{\mu \pm i\omega x}$ will be 2 solutions integers, and in the case of second order differential equation we reorganize it and found the 2 solutions in a different manner there was $e^{\mu x}$ into $\cos \omega x$ and $e^{\mu x}$ into $\sin \omega x$.

So, these 2 will be the corresponding 2 linearly independent solutions of this homogenous equation. Now, if we get a real root which is repeated and if its multiplicity is r then we will find that $e^{\gamma x}$, $x e^{\gamma x}$, $x^2 e^{\gamma x}$ and so on up to $x^{r-1} e^{\gamma x}$ all these will give us r linearly independent solutions of this, this is something which you can prove which you can show.

Similarly, for every pair of complex roots which appears repeated, you will have similar additional linearly independent solutions for example, if you $\mu \pm i\omega$ appears twice. So, that should account for four linearly independent solutions. So, first pair is $e^{\mu x} \cos \omega x$, $e^{\mu x} \sin \omega x$ and the next pair will be these two multiplied with x . Similarly if it appears thrice the third pair will appear with $x^2 e^{\mu x} \cos \omega x$ and $x^2 e^{\mu x} \sin \omega x$ and so on.

So, with multiplicity r you will go up to x^{r-1} power. So, this way if you determine the solutions n solutions of this binomial equation, then from that you can determine n linearly independent solutions of this homogeneous differential equation. Now, after having the solutions in this manner, you want to find out the solution corresponding to the solution for the non homogeneous equation with this whole thing equal to some $R(x)$. Now, if the equation is with constant coefficients like this and $R(x)$ is

one of those chosen functions for the right hand side that is one of those special functions, binomial exponential sinusoid or their mutual combinations then the method of undetermined coefficients will give you a solution that is for this.

Mathematical Methods in Engineering and Science Higher Order Linear ODE's 10.11

Theory of Linear ODE's
Homogeneous Equations with Constant Coefficients
Non-Homogeneous Equations
Substituting, Equations of Higher Order

Non-Homogeneous Equations

Method of undetermined coefficients

$$y^{(n)} + a_1 y^{(n-1)} + a_2 y^{(n-2)} + \dots + a_{n-1} y' + a_n y = R(x)$$

Extension of the second order case

Method of variation of parameters

$$y_p(x) = \sum_{i=1}^n u_i(x) y_i(x)$$

Imposed condition	Derivative
$\sum_{i=1}^n u_i'(x) y_i(x) = 0$	$\Rightarrow y_p'(x) = \sum_{i=1}^n u_i(x) y_i'(x)$
$\sum_{i=1}^n u_i'(x) y_i'(x) = 0$	$\Rightarrow y_p''(x) = \sum_{i=1}^n u_i(x) y_i''(x)$
...	...
$\sum_{i=1}^n u_i'(x) y_i^{(n-2)}(x) = 0$	$\Rightarrow y_p^{(n-1)}(x) = \sum_{i=1}^n u_i(x) y_i^{(n-1)}(x)$

Finally, $y_p^{(n)}(x) = \sum_{i=1}^n u_i'(x) y_i^{(n-1)}(x) + \sum_{i=1}^n u_i(x) y_i^{(n)}(x)$

$$\Rightarrow \sum_{i=1}^n u_i'(x) y_i^{(n-1)}(x) + \sum_{i=1}^n u_i(x) [y_i^{(n)} + P_1 y_i^{(n-1)} + \dots + P_n y_i] = R(x)$$

So, method of undetermined coefficients will work exactly as the extension of the second order case. Here also those things those modification rules will apply that is even if this happens to be e to the power gamma x, but then if e to the power gamma x happens to be already there in the basis for solution of this, then rather than proposing e to the power gamma x you will propose x into e to the power gamma x.

Similarly, if e to the power gamma x e to the power gamma x and so on up to x to the power r minus 1 e to the power gamma x up to this if all of these are sitting already in the basis for the solution of this. Then even if e to the power gamma x appears in the right hand side function you will have to propose as yp x to the power r e to the power gamma x there is a next into some constant and so on. So, this is a general rule.

Now, measure of undetermined coefficients is something which will work exactly as in the case of second order equation and as you know that in the general case with general right hand side function and functions appearing in the place of coefficients a 1 a 2 a 3 this will not be sufficient. For those purposes for those situations you will need the more general method which is the method of variation of parameters, which will work in the general case that is in this case that will work in this case as well.

So, for that for solving that we will consider a linear combination like this now let us. So, we propose a function of this kind which is a linear combination of all these n functions y_1 to y_n , which are known to be the basis members of the corresponding solution of the homogenous equation, basis members of the solution of the corresponding homogenous equation.

(Refer Slide Time: 25:54)

The chalkboard contains the following mathematical content:

$$y^{(n)} + P_1 y^{(n-1)} + P_2 y^{(n-2)} + \dots + P_{n-1} y' + P_n y = R(x)$$

Proposed: $y_p(x) = u_1 y_1 + u_2 y_2 + \dots + u_n y_n$

$$\begin{bmatrix} y_1 & y_2 & y_3 & \dots & y_n \\ y_1' & y_2' & y_3' & \dots & y_n' \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ y_1^{(n-1)} & y_2^{(n-1)} & y_3^{(n-1)} & \dots & y_n^{(n-1)} \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \\ u_3 \\ \vdots \\ u_n \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ \vdots \\ 0 \end{bmatrix} R(x)$$

That is the solutions of this. So, n linearly independent solutions of this equal to 0 is y_1 y_2 etcetera. So, y_p is proposed like this.

Now, we differentiate this and eventually we will differentiate it n times and insert all the functions and derivatives into this equation, in order to find the solution find a particular solution of the non-homogeneous equation. Now, as we differentiate first time we find that the derivative of these n terms will get us 2 n terms. In the first n terms we will have u_i prime y_i and the other n terms will be $u_i y_i$ prime. Now, we try to put additional condition that this is 0. So, when this part is 0 then the first derivative of this will turn out to be as $u_i y_i$ prime.

Now, this is 0 means basically that the rate of the function u is orthogonal through the vector function in the vector space sense that is if u of x is a vector function with components u_1 u_2 etcetera, then u prime will be its derivative its rate and that rate is orthogonal to the vector function y of x. So, that is the condition we have imposed and that gives us y_p prime which is like this. Now note that this condition turns out to be the

first row from this matrix vector equation, y_1 into u_1' plus y_2 into u_2' and so on y_n into u_n' equal to 0 that is essentially this condition.

Now, imposing this condition we get the first derivative as this which is free from u prime terms which means that its derivative will be free from u double prime terms. So, we find out its derivative and as we try to put its derivatives in that they will be again 2 n terms n terms together are taken as 0 that is the second condition that we have imposed. So, as we impose that the from the derivative of this u prime y prime terms the sum of those terms vanish that is the condition we impose and the rest of the 2 terms u into y double prime that remain here.

Now, this condition is equivalent to the second row that is $\sum y_i' u_i'$, y_1' into u_1' plus y_2' into u_2' and so on is equal to 0, that is the second row in this matrix vector equation. Similarly we go on differentiating the derivatives further at every step we go on imposing these conditions in the $n - 1$ derivative that gets involved here and corresponding $n - 1$ th derivative we get here, and this is the point this is the stage where we have to find the last derivative that is needed that is $y_n^{(n)}$.

So, when we differentiate this we get the full derivative in which full 2 n terms from u_i' $y_i^{(n-1)}$ plus u_i into $y_n^{(n)}$. So, these 2 both the terms will appear here in the n th derivative. So, note that from this point till this point there are $n - 1$ conditions that have been imposed with the function the first derivative second derivative up to $n - 2$ th derivative. So, these are $n - 1$ conditions that have been imposed these are the top $n - 1$ rows from here involving in the coefficients here up to the $n - 2$ th derivatives.

The last equation we will get when we insert this $y_n^{(n)}$ this expression and all these expressions for the previous derivatives and the function itself also. So, when we put all of these expressions, now into this differential equation given then what we do? We add to this last equation p_1 times this plus p_2 times the previous 1 plus p_3 times the still previous 1 and so on finally, p_{n-2} times this plus p_{n-1} times this plus p_n times this that is from here. As we do that and collect the terms together then this term is here this term is here $u_1' y_n^{(n-1)}$ ok.

And here the other terms that is this into this plus p 1 into this plus p 2 into previous 1 and so on. So, there you will find that u is common in all these even up to this. So, in the that is why u has been u_i has been kept common outside and inside the bracket you have y_i plus p 1 into the y_i n minus 1 th derivative and plus p 2 into y_i n minus 2 th derivative and so on that is this actually. Now we know that each of the functions y₁ y₂ y₃ y₄ etcetera are solutions of the homogeneous equation corresponding homogeneous equation that is this equal to 0.

And therefore, for every i separately this bracketed term vanishes. So, this whole thing goes to 0 this remains on the left side left hand side and R x remains on the right hand side and that is why we get this last row from this system of equations and what is the matrix sitting here this is our old friend that is the fundamental matrix capital Y that we constructed from the state vectors of these n linearly independent solutions of the corresponding homogeneous equation these are the columns. So, here is our fundamental matrix capital Y of x.

(Refer Slide Time: 32:55)

Mathematical Methods in Engineering and Science Higher Order Linear ODE's 2014
Theory of Linear ODE's
Homogeneous Equations with Constant Coefficients
Non-Homogeneous Equations
Euler-Cauchy Equation of Higher Order

Non-Homogeneous Equations

Since each $y_i(x)$ is a solution of the HE,

$$\sum_{i=1}^n u'_i(x) y_i^{(n-1)}(x) = R(x).$$

Assembling all conditions on $\mathbf{u}'(x)$ together,

$$[\mathbf{Y}(x)] \mathbf{u}'(x) = \mathbf{e}_n R(x).$$

Since $\mathbf{Y}^{-1} = \frac{\text{adj } \mathbf{Y}}{\det[\mathbf{Y}]}$,

$$\mathbf{u}'(x) = \frac{1}{\det[\mathbf{Y}(x)]} [\text{adj } \mathbf{Y}(x)] \mathbf{e}_n R(x) = \frac{R(x)}{W(x)} [\text{last column of adj } \mathbf{Y}(x)].$$

Using cofactors of elements from last row only,

$$u'_i(x) = \frac{W_i(x)}{W(x)} R(x).$$

with $W_i(x)$ = Wronskian evaluated with \mathbf{e}_n in place of i -th column.

$$u_i(x) = \int \frac{W_i(x) R(x)}{W(x)} dx$$

So this is the last equation and this is the assembled matrix vector equation together Y of x this matrix into the vector u prime is equal to this vector with all zeroes and R x at the last entry.

That can be said as e_n into R x which will mean that last one is one and here we have R x it is the same thing. So, this is the e_n that is the last natural identity member in the n

dimensional rates. So, now, this is the matrix vector equation in the rates u prime and this matrix is non singular because these solutions form a basis; that means, they are all linearly independent. So, this matrix is non-singular as its Wronskian is non-zero. So, this non singular matrix can be inverted and this matrix vector equation can be solved.

Now, usually I have told you earlier that in the context of linear algebra that the computation of inverse numerical computation of inverse with the help of this formula is typically inefficient, but here we are doing the analysis in terms of not numbers, but in terms of expressions and in this context this is this formula turns out to be of advantage. So, inverse of Y is adjoint by determinant right. So, if we use that then the adjoint by determinant will come here and we can calculate u prime x . So, that is 1 by determinant into adjoint into this side.

Now, note that this adjoint matrix will be multiplied with a vector immediately, which has all its entries 0 except the last one. So, from the adjoint only your last column is needed that is adjoint y into e_n will essentially mean the last column of adjoint y so; that means, when we construct adjoint y we do not construct the entire adjoint of this matrix, but we need to construct only the last column of it. So, last column of its adjoint will mean will require the cofactors of only the last row because adjoint will be the matrix formed by the cofactors of this matrix transposed.

So, the last column of the adjoint will be formed by the cofactors of the last row. So, last column of the adjoint matrix is what we will need that is adjoint into e_n . So, for that we will find out the cofactors of the elements from the last row only. Now, what is the cofactor of this entry for the cofactor of this entry we will need to remove this column and this row and whatever remains. For that we have to find the determinant and then we will put the sign according to the row number column number of this, that is as which is the row number n and $1\ 2\ 3$ that is the column number.

So; that means, the position of this will reflecting the sign and other than that this column and this row will be removed. So, the cofactor of this this element we can get by replacing this column with $0\ 0\ 0\ 0\ 0\ 1$ because this column anyway will be removed. So, if we put 1 here then as we remove this row and this column the rest of the determinant will give us the correct cofactor with the sign that we will get from the position. So that means, if we put if we replace this third column with e_n that is $0\ 0\ 0\ 0\ 1$

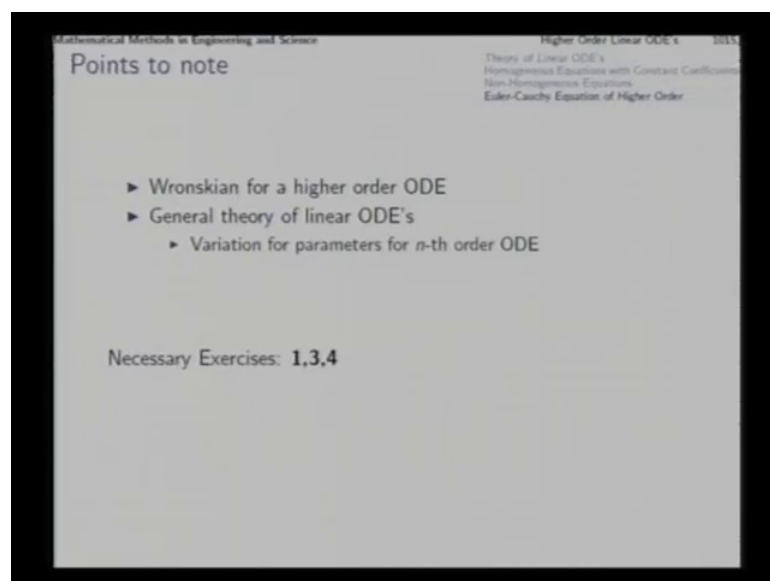

here, then the determinant of this itself will be that cofactor because the in that general computation through this column we will get only one term which is 1 into the rest of it which is the correct minor and the position we will get from the expression or the determinant anywhere.

So; that means, that the entries the first second third entry will be given as $w_1 w_2 w_3$, when W_i is the same Wronskian same determinant of this matrix when evaluated with e_i in place of the i th column. So, this gives us the expression for u_i prime and then when we find that this is a function of x only then we can evaluate u_i as direct quadrature direct integration and then this set of $u_1 u_2 u_3 u_4$ when inserted in the original proposal gives us a particular solution of this non homogeneous equation.

So, this is the way we develop the general solution for a non homogeneous equation that is we first develop the general solution of the corresponding homogenous equation by replacing the r with 0 from that we find out the basis for all solutions of that homogenous equation, that basis y_1 to y_n we use to propose a solution of the non homogeneous equation including the Rx . And then based on this and based on that means, based on this expression which determine the proposed coefficients coefficient functions $u_1 u_2$ etcetera and then this gives us 1 solution of the non-homogeneous equation.

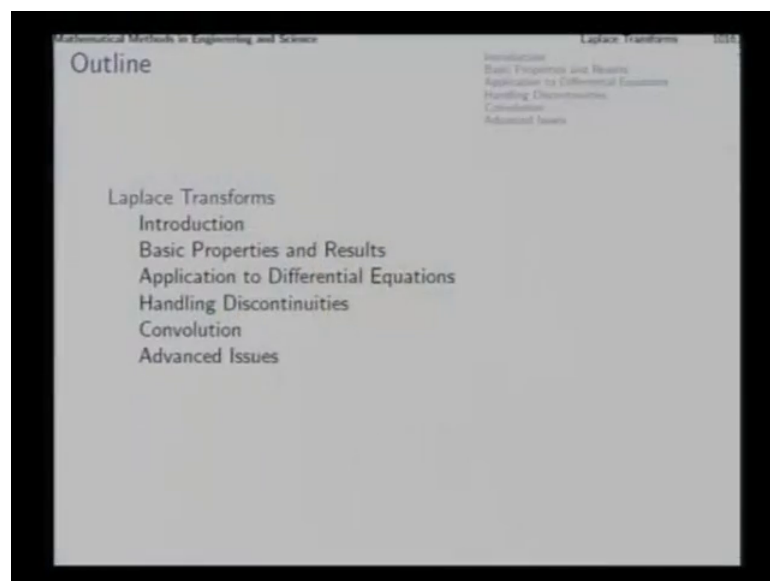

And then y_i plus y_p gives us the complete solution for the non homogeneous equation.

(Refer Slide Time: 39:11)

Now many of these issues that is the Wronskian for the higher order ODE or the basis for describing the solutions of the homogenous equation, and then the way these basis members can be used to find a particular solution of the general non homogeneous equation; all these will find similar analogous situations when we discuss the solution of systems of ordinary differential equations in the next lecture. But currently in the remaining time of this lecture we will take a small digression into another topic which is in a way complementary to this classical framework of solving linear ordinary differential equation, and that is the paradigm of Laplace transform method.

(Refer Slide Time: 40:07)

Till now in the classical framework of solution of ordinary differential equations we have typically discussed with the understanding that the entire differential equation is known in advance.

(Refer Slide Time: 40:17)

Mathematical Methods in Engineering and Science Laplace Transforms 10/11

Introduction

Classical perspective

- ▶ Entire differential equation is known in advance.
- ▶ Go for a complete solution first.
- ▶ Afterwards, use the initial (or other) conditions.

A practical situation

- ▶ You have a plant
 - ▶ intrinsic dynamic model as well as the starting conditions.
- ▶ You may drive the plant with different kinds of inputs on different occasions.

Implication

- ▶ Left-hand side of the ODE and the initial conditions are known *a priori*.
- ▶ Right-hand side, $R(x)$, changes from task to task.

That is both the left hand side which has terms related to y and its derivative and the right hand side $R(x)$. So, the entire differential equation is known in advance, this is the typical understanding with which till now we have developed the methods and the typical way to look for the solution in the previous few lectures including the current one has been to go for a complete solution first. And after getting the complete solution then if the conditions are available initial or boundary conditions then we can impose those conditions to find out the arbitrary constants arising out of the solution process.

Now this is the typical classical perspective; however, there can be practical situations where you already have a plant, you already have a physical system which means that you know the left hand side of this differential equation completely. Now that particular system that particular plant can be operated with different kinds of inputs which means this $R(x)$ can vary from one application to another that can be a practical situation.

So, you have the plant or system means that its intrinsic dynamic model you know and for that matter you know the starting condition, that is from which initial condition for this initial position, for this initial first rate second rate up to n minus 1th rate. So, all those things are known. Now as you decide to plug in different kinds of inputs you will be basically changing the right hand side so; that means, that as you drive the plant with different kinds of inputs on different occasions, you will be changing the right hand side

without changing the left hand side of the differential equation and without changing the initial conditions.

So; that means, that entire differential equation is not known in advance only the left side of it is known the input function side is not known in advance that can change from one application to another. On the other hand the point of using the initial conditions afterwards does not sound so nice because we know the initial conditions beforehand. So, in such a situation another way of solution which takes care of the left side of the differential equation and the initial conditions first in one framework, and depending upon the right hand side the last amount of last part of the word can be accomplished differently in different situations that is a paradigm shift.

So, with the left hand side of the ODE known, an initial conditions are known a priori. So, right hand side $R(x)$ changes from task to task. So, Laplace transform methods give you a method which takes care of this part completely and keeps the job half done waiting for the right hand side to appear at any time. So, as a different right hand side appears every time the solution can be changed by another little amount of additional work. Apart from that there is another question that may be asked which is answered properly and adequately by Laplace transform methods and not so, well by the methods that we have been discussing till now.

(Refer Slide Time: 44:04)

Mathematical Methods in Engineering and Science

Introduction

Another question: What if $R(x)$ is not continuous?

- ▶ When power is switched on or off, what happens?
- ▶ If there is a sudden voltage fluctuation, what happens to the equipment connected to the power line?

Or, does "anything" happen in the immediate future?
"Something" certainly happens. The IVP has a solution!

Laplace transforms provide a tool to find the solution, in spite of the discontinuity of $R(x)$.

Integral transform:

$$T[f(t)](s) = \int_a^b K(s, t)f(t)dt$$

s: frequency variable
 $K(s, t)$: kernel of the transform

Note: $T[f(t)]$ is a function of s , not t .

And that is suppose this $R(x)$ is not continuous, till now we have been relying upon the existence and uniqueness results which use the notion that all these coefficient functions and $R(x)$ are continuous and bounded. Now suppose the input function with which we try to drive the plant try to drive the system is not continuous. So, for example, when power is suddenly switched off or switched on the if the power if the plug is giving you the input function $R(x)$ and as it is suddenly switched on or suddenly switched off, there is a discontinuity at $R(x)$ say x is representing time here ok.

So, as power is switched on or off what happens? What happens is the question that we asked when we posed an initial value problem. So, this initial value problem is it well posed. So, we are asking this question that what happens, what is the future evolution of y of t y of x in this context. Now when we ask is this question is this initial value problem well posed then we say that does a solution to the differential equation exist or does the solution is the solution unique and so on. Apart from switching on or off if there is a sudden voltage fluctuations.

Suppose the voltage is somehow related to this input function input function of time. So, with time as the voltage fluctuate in a in the appliance in some appliance the model, the dynamic model of which is sitting here then we say that the equipment the appliance which is connected to the power line what happens to its state how does the state evolve with time. Now asking does anything happen in the immediate future that is the mathematical the mathematical equivalent of this question does anything happen in the immediate future is basically the question, that for this initial value problem does there exist a solution.

Now, this question is named because something will certainly happen. So, as something certainly happens we say that this initial value problem certainly has a solution. Now depending on the $R(x)$ being continuous and bounded may not help to find the solution since at situation. So, Laplace transforms provide a tool to find the solution in spite of the discontinuity of the right hand side function $R(x)$ through certain ways of handling discontinuity. So, let us quickly have a have an overview of the Laplace transform technique the main salient features of it, before we proceed to the system of ordinary differential equations.

Laplace transform happens to be one particular kind of integral transform of this kind, where there is a there is an integral there is a kernel function and $f(t)$ function for which we are looking for the transform. So, this resulting function $F(s)$ of $f(t)$ is actually not a function of t because integration with respect to t has been carried over carried out to get that transform function. The transform function will have the other variable s which is typically called the frequency variable.

(Refer Slide Time: 47:36)

Mathematical Methods in Engineering and Science Laplace Transforms 1103

Introduction

With kernel function $K(s, t) = e^{-st}$, and limits $a = 0$, $b = \infty$.

Laplace transform

$$F(s) = L\{f(t)\} = \int_0^{\infty} e^{-st} f(t) dt = \lim_{b \rightarrow \infty} \int_0^b e^{-st} f(t) dt$$

When this integral exists, $f(t)$ has its Laplace transform.

Sufficient condition:

- ▶ $f(t)$ is piecewise continuous, and
- ▶ it is of exponential order, i.e. $|f(t)| < Me^{ct}$ for some (finite) M and c .

Inverse Laplace transform:

$$f(t) = L^{-1}\{F(s)\}$$

So, with the kernel function like this and limits of integration from 0 to infinity we have what is called the Laplace transform defined by this formula.

In which case this integral this improper integral is evaluated in this now under certain conditions the a function $f(t)$ has a Laplace transform and the corresponding inverse function is called the Inverse Laplace transform of a function of the frequency variable fs . So, if fs is the Laplace transform of $f(t)$ then $f(t)$ is called the inverse Laplace transform of fs . Now with some background work people have developed some long tables of Laplace transforms and inverse Laplace transforms which we can keep as reference.

Linearity:

$$L\{af(t) + bg(t)\} = aL\{f(t)\} + bL\{g(t)\}$$

First shifting property or the frequency shifting rule

$$L\{e^{at}f(t)\} = F(s - a)$$

Laplace transforms of some elementary functions:

$$L\{1\} = \int_0^{\infty} e^{-st} dt = \left[\frac{e^{-st}}{-s} \right]_0^{\infty} = \frac{1}{s}$$

$$L\{t\} = \int_0^{\infty} e^{-st} t dt = \left[t \frac{e^{-st}}{-s} \right]_0^{\infty} + \frac{1}{s} \int_0^{\infty} e^{-st} dt = \frac{1}{s^2}$$

$$L\{t^n\} = \frac{n!}{s^{n+1}} \quad (\text{for positive integer } n)$$

$$L\{t^a\} = \frac{\Gamma(a+1)}{s^{a+1}} \quad (\text{for } a \in \mathbb{R}^+)$$

and $L\{e^{at}\} = \frac{1}{s - a}$

So, right now I am omitting the details of this.

$$L\{\cos \omega t\} = \frac{s}{s^2 + \omega^2}, \quad L\{\sin \omega t\} = \frac{\omega}{s^2 + \omega^2}$$

$$L\{\cosh at\} = \frac{s}{s^2 - a^2}, \quad L\{\sinh at\} = \frac{a}{s^2 - a^2}$$

$$L\{e^{\mu t} \cos \omega t\} = \frac{s - \mu}{(s - \mu)^2 + \omega^2}, \quad L\{e^{\mu t} \sin \omega t\} = \frac{\omega}{(s - \mu)^2 + \omega^2}$$

Laplace transform of derivative:

$$L\{f'(t)\} = \int_0^{\infty} e^{-st} f'(t) dt$$

$$= [e^{-st} f(t)]_0^{\infty} + s \int_0^{\infty} e^{-st} f(t) dt = sL\{f(t)\} - f(0)$$

Using this process recursively,

$$L\{f^{(n)}(t)\} = s^n L\{f(t)\} - s^{(n-1)} f(0) - s^{(n-2)} f'(0) - \dots - f^{(n-1)}(0)$$

For integral $g(t) = \int_0^t f(t) dt$, $g(0) = 0$, and

$$L\{g'(t)\} = sL\{g(t)\} - g(0) = sL\{g(t)\} \Rightarrow L\{g(t)\} = \frac{1}{s} L\{f(t)\}$$

And going directly to the typical methodology of solution solving differential equations with the help of the Laplace transform method.

(Refer Slide Time: 48:34)

Mathematical Methods in Engineering and Science Laplace Transforms 2021

Application to Differential Equations

Example:
Initial value problem of a linear constant coefficient ODE
$$y'' + ay' + by = r(t), \quad y(0) = K_0, \quad y'(0) = K_1$$

Laplace transforms of both sides of the ODE:
$$s^2Y(s) - sy(0) - y'(0) + a[sY(s) - y(0)] + bY(s) = R(s)$$
$$\Rightarrow (s^2 + as + b)Y(s) = (s + a)K_0 + K_1 + R(s)$$

A differential equation in $y(t)$ has been converted to an algebraic equation in $Y(s)$.

Transfer function: ratio of Laplace transform of output function $y(t)$ to that of input function $r(t)$, with zero initial conditions

$$Q(s) = \frac{Y(s)}{R(s)} = \frac{1}{s^2 + as + b} \quad (\text{in this case})$$
$$Y(s) = [(s + a)K_0 + K_1]Q(s) + Q(s)R(s)$$

Solution of the given IVP: $y(t) = L^{-1}\{Y(s)\}$

So, suppose this is the linear differential equation with constant coefficients and these are the initial conditions, second order differential equation the 2 initial conditions will be needed. Now if we take the Laplace transform of both sides of this using the rules for Laplace transforms of derivatives and in that how initial conditions appear etcetera etcetera we will get the Laplace transform of both sides of this equation in this manner. s^2 plus as plus b times $Y(s)$ where $Y(s)$ is the Laplace transform of the unknown function y this is what we want to determine and on this side we will have s plus aK_0 plus K_1 plus $R(s)$. Now, up to this point we can do except for this $R(s)$ even without knowledge of this right hand function $R(t)$. The important point to note here is that this differential equation has been broken down to an algebraic equation and from here we can solve for $Y(s)$ in terms of the other quantity.

So, this whole thing divided by $Y(s)$ will be the solution that is rather than the solution it will be the Laplace transform of the solution. So, even without knowing the solution $y(t)$ we know the Laplace transform of the $Y(s)$. So, then the next step will be after knowing $R(s)$ also if we know the $R(s)$ also, then this whole thing together that is the inverse of it this is $Q(s)$. So, that is why $Q(s)$ has been put here. So, then as we solve for $Y(s)$ from this algebraic equation of in capital $Y(s)$ then we have the Laplace transform of $Y(t)$. So, its inverse Laplace transform turns out to be the solution.

So, in this the initial conditions have been involved from the very beginning and inversion of the Laplace transform is conducted at the end to resurrect the solution. Now in this framework of course, we can handle only limited number of plants with constant coefficients and so on easily, but then we can handle discontinuity of Rt through 2 important functions and their Laplace transforms.

(Refer Slide Time: 51:02)

Mathematical Methods in Engineering and Science Laplace Transforms 2024

Handling Discontinuities

Introduction
Basic Properties and Results
Applications to Differential Equations
Handling Discontinuities
Conclusion
Advanced Issues

Unit step function

$$u(t-a) = \begin{cases} 0 & \text{if } t < a \\ 1 & \text{if } t > a \end{cases}$$

Its Laplace transform:

$$L\{u(t-a)\} = \int_0^{\infty} e^{-st} u(t-a) dt = \int_0^a 0 \cdot dt + \int_a^{\infty} e^{-st} dt = \frac{e^{-as}}{s}$$

For input $f(t)$ with a time delay,

$$f(t-a)u(t-a) = \begin{cases} 0 & \text{if } t < a \\ f(t-a) & \text{if } t > a \end{cases}$$

has its Laplace transform as

$$\begin{aligned} L\{f(t-a)u(t-a)\} &= \int_a^{\infty} e^{-st} f(t-a) dt \\ &= \int_0^{\infty} e^{-s(a+\tau)} f(\tau) d\tau = e^{-as} L\{f(t)\}. \end{aligned}$$

Second shifting property or the time shifting rule

So, this is the unit step function if t is greater than a less than a the value is 0, if t is greater than a then its value is 1 and its Laplace transform has been determined and it is found to be this.

Now, if a function appears with a time delay after time a then this is its effect and for that this can be the detailed expression and for which we can work out the Laplace transform in terms of the Laplace transform of the original function, that is what is the shift in time that is the result of the shift in time. This is one important discontinuous function for which we have the Laplace transforms to be used whenever this kind of an input appears it is suddenly applied and then after application that value is known.

(Refer Slide Time: 52:05)

Mathematical Methods in Engineering and Science Laplace Transforms 2023

Handling Discontinuities

In the limit,

$$\delta(t-a) = \lim_{k \rightarrow 0} f_k(t-a)$$

or,
$$\delta(t-a) = \begin{cases} \infty & \text{if } t = a \\ 0 & \text{otherwise} \end{cases} \quad \text{and} \quad \int_0^{\infty} \delta(t-a) dt = 1.$$

Unit impulse function or Dirac's delta function

$$\begin{aligned} L\{\delta(t-a)\} &= \lim_{k \rightarrow 0} \frac{1}{k} [L\{u(t-a)\} - L\{u(t-a-k)\}] \\ &= \lim_{k \rightarrow 0} \frac{e^{-as} - e^{-(a+k)s}}{ks} = e^{-as} \end{aligned}$$

Through step and impulse functions, Laplace transform method can handle IVP's with discontinuous inputs.

Another important discontinuous function is this Dirac's delta function.

Suddenly there is a huge jump in the value of r . So, and that value is suddenly at that particular moment the value is infinite very large every at other all other time it is 0 and with the special property that under that curve we have under that huge slash we have the area as unity. So, this is the Dirac's delta function or unit impulse function. So, for this also the Laplace transform has been determined and that turns out to be this. Now with the help of these 2 discontinuous functions and their Laplace transforms, we can handle the situations where the right hand side function of the differential equation is discontinuous.

So, through step functions and step function and impulse function Laplace transform method can handle initial value problems with discontinuous inputs as well. Now another important term is there which appears quite often in the discussion of Laplace transform method and that is convolution.

(Refer Slide Time: 53:21)

Mathematical Methods in Engineering and Science Laplace Transforms 1041

Convolution

A generalized product of two functions

$$h(t) = f(t) * g(t) = \int_0^t f(\tau)g(t-\tau) d\tau$$

Laplace transform of the convolution:

$$H(s) = \int_0^\infty e^{-st} \int_0^t f(\tau)g(t-\tau) d\tau dt = \int_0^\infty f(\tau) \int_\tau^\infty e^{-st} g(t-\tau) dt d\tau$$

(a) Original order (b) Changed order

Figure: Region of integration for $L\{h(t)\}$

Convolution of 2 functions is actually a kind of a generalized product of 2 functions which is defined in this manner. Now you can show that the Laplace transform of the convolution is actually the product of the corresponding Laplace transforms that is this.

(Refer Slide Time: 53:47)

Mathematical Methods in Engineering and Science Laplace Transforms 1041

Convolution

Through substitution $t' = t - \tau$,

$$H(s) = \int_0^\infty f(\tau) \int_0^\infty e^{-s(t'+\tau)} g(t') dt' d\tau$$

$$= \int_0^\infty f(\tau) e^{-s\tau} \left[\int_0^\infty e^{-st'} g(t') dt' \right] d\tau$$

$H(s) = F(s)G(s)$

Convolution theorem:
 Laplace transform of the convolution integral of two functions is given by the product of the Laplace transforms of the two functions.

Utilities:

- ▶ To invert $Q(s)R(s)$, one can convolute $y(t) = q(t) * r(t)$.
- ▶ In solving some integral equation.

If you have 2 functions F and G and their convolution of is a then the Laplace transform of the convolution turns out to be the product of the 2 individual Laplace transforms this is called the convolution theorem. Laplace transform of the convolution integral of 2 functions it is given by the product of the Laplace transform of the 2 functions.

(Refer Slide Time: 54:16)

Mathematical Methods in Engineering and Science Laplace Transforms 11/11

Application to Differential Equations

Example:
Initial value problem of a linear constant coefficient ODE

$$y'' + ay' + by = r(t), \quad y(0) = K_0, \quad y'(0) = K_1$$

Laplace transforms of both sides of the ODE:

$$s^2 Y(s) - sy(0) - y'(0) + a[sY(s) - y(0)] + bY(s) = R(s)$$
$$\Rightarrow (s^2 + as + b)Y(s) = (s + a)K_0 + K_1 + R(s)$$

A differential equation in $y(t)$ has been converted to an algebraic equation in $Y(s)$.

Transfer function: ratio of Laplace transform of output function $y(t)$ to that of input function $r(t)$, with zero initial conditions

$$Q(s) = \frac{Y(s)}{R(s)} = \frac{1}{s^2 + as + b} \quad (\text{in this case})$$
$$Y(s) = [(s + a)K_0 + K_1]Q(s) + Q(s)R(s)$$

Solution of the given IVP: $y(t) = L^{-1}\{Y(s)\}$

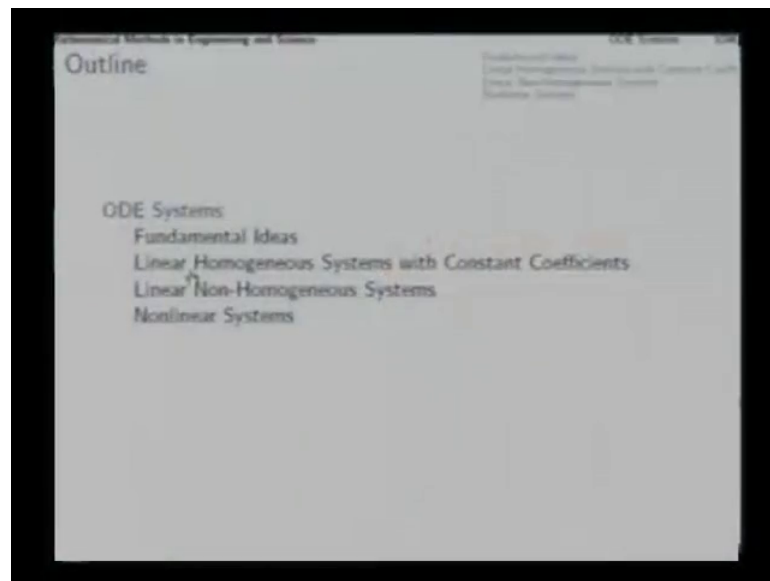

Now quite often what happens is that in this context we know $Q(s)R(s)$ and we know that the moment we say in this particular case, if the initial conditions were $0, K_0$ and K_1 then these 2 terms will be 0 and this whole thing will go up and; that means, after this step with K_0 and K_1 as 0 we can invert this and find out $Q(s)$ and that is that gives us $Y(s)$ as $Q(s)R(s)$.

Now, rather than finding $R(s)$ there is after the input function $R(t)$ has been specified, then rather than finding its Laplace transform $R(s)$ multiplying that with $Q(s)$ and then taking the inverse Laplace transform one could do well to directly find out the convolution integral of $Q(t)$ original $Q(t)$ and $R(t)$, that is because the inverse Laplace transform of $Q(s)R(s)$ which we want will be the same as the convolution integral of the original functions in time $Q(t)R(t)$. So, in that sense in many cases when the $R(t)$ changes then rather than waiting for $R(t)$ to appear and then compute $R(s)$ quite often, from $Q(s)$ itself the transfer function itself this is called the transfer function.

From the transfer function itself we find out the corresponding $Q(t)$ through its inverse Laplace transform and keep it, and then the moment a new input function $R(t)$ is supplied then we do not go into Laplace transform further. So, rather than going to Laplace transform to find $R(s)$ then multiplying this and then taking the inverse Laplace transform, we can simply take the new $R(t)$ and the originally earlier determined $Q(t)$ and construct their convolution through the definition of the convolution integral.

So, this is the another important issue which appears in the analysis of Laplace transform method and this will again appear when we later study Fourier transform. So, with this little discussion on Laplace transform, we continue we will continue in the next lecture to the solution of ordinary differential equation systems. So, ODE systems we will take up in our next lecture and from there we will discuss the stability of dynamic systems which will be solving through these methods.

(Refer Slide Time: 56:57)

Thank you.
