Lecture 24
Review of Fluid Mechanics - V

Good afternoon. Last class, we were discussing the exact solutions of Navier-Stokes equation and we appreciated the fact that in certain special cases of steady incompressible laminar fully developed flow, the Navier-Stokes equation is converted to ordinary linear differential equation. This is because of the fact that the inertial terms in the left-hand side of the Navier-Stokes equation identically vanishes. So therefore, it is possible to have a close form solution by integrating the resulting Navier-Stokes equation and we have already discussed the situation like Couette flow.

(Refer Slide Time: 01:14)

Today we will discuss Plane Poiseuille Flow we will discuss and it is very simple when we discuss the Couette flow, so it will automatically come. The plane Poiseuille flow, first of all we have to define what is plane Poiseuille flow. This is the name of a scientist. He is a great person in fluid mechanics. So, this flow is like this, this is again a steady incompressible laminar fully developed flow between two plates which are stationary, that means two fixed plates.

In Couette flow, one of the plates was moving with a velocity related to the other. So that the flow was caused by shear at the same time pressure gradient if it is imposed. But here since the two plates are held stationary, the flow takes place only by virtue of the pressure gradient. So, in this case if we remember that, if we take the axis like this, this is our x and this is our y. Now, since by geometry of the flow, this is symmetrical with respect to the central line.

Because the two plates are at rest, the identical kinematic bounded conditions. So therefore, it is convenient to use this as the axis x at the center line, y and z

(Refer Slide Time: 03:35)

$\mu \frac{d^2 u}{dy^2} = \frac{dp}{dx}$
 $\frac{du}{dy} = \frac{1}{\mu} \frac{dp}{dx} y + C_1$
 $u = \frac{1}{2\mu} \frac{dp}{dx} y^2 + C_1 y + C_2$
 at $y = \pm h/2$ $u = 0$
 at $y = 0$ $du/dy = 0$

Now in general, we have already developed that in Cartesian coordinate system, for this situations of exact solutions our Navier-Stokes equation becomes $\mu \frac{d^2 u}{dy^2} = \frac{dp}{dx}$, this already we appreciated $\frac{dp}{dx}$ by definition 0, there is no velocity in the jet component and the width of the channel is so large compared to this spacing or the height and here we define this as h, total spacing, that the change of any parameter with respect to J is negligible compared to X and Y.

So, with all these assumptions we have found that u is a function of y only and p is a function of x only and this is the equation resulting from the x direction Navier-Stokes equation and since p is a function of x then u is a function y they are constant, all these things were derived the last class and if we integrate it we get $\frac{du}{dy} = \frac{1}{\mu} \frac{dp}{dx} y$, all these things we did earlier plus C_1 .

And the next one is that u is equal to $\frac{1}{2\mu} \frac{dp}{dx} y^2 + c_1 y + c_2$. So, therefore any such situation of steady laminar fully developed incompressible flow, this is a common equation with respect to a Cartesian coordinate system in general. So c_1 , c_2 will change according to the definition of flow by geometry. So, plane Poiseuille flow is specified by the two fixed plates.

So therefore, our boundary condition will be at y is equal to plus minus $h/2$ that means that 2 walls $h/2$ and minus $h/2$ since we are taking the x axis along the center line. Clear? No slip condition demands u is equal to 0. Since the flow is axis symmetric about this center line then we can write at y is equal to 0, $du/dy = 0$. And this comes from the physical strength that it is symmetry and if we take this type of axis that is plus $h/2$ minus $h/2$.

We have got, we have the same raisers which means that c_1 has to be zero mathematically that $y = 0$ dy is zero. That means there cannot be any term containing the first part of y .

(Refer Slide Time: 06:44)

The image shows a green chalkboard with handwritten mathematical derivations. At the top left, it says $\mu \frac{d^2 u}{dy^2} = \text{constant}$. Below this, the general solution is written as $\frac{1}{2\mu} \frac{dp}{dx} y^2 + c_1 y + c_2$. A boxed section shows the boundary conditions: $\frac{dp}{dx} y^2 + c_1 y + c_2 = 0$ and $\frac{du}{dy} = 0$. To the right, the velocity profile is derived as $u = \frac{h^2}{8\mu} \left(-\frac{dp}{dx} \right) \left(1 - \frac{4y^2}{h^2} \right)$. Below this, it is written as $u = \frac{h^2}{8\mu} \left(-\frac{dp}{dx} \right) \left[1 - \frac{y^2}{(h/2)^2} \right]$. At the bottom, the maximum velocity is given as $u_{max} = \frac{h^2}{8\mu} \left(-\frac{dp}{dx} \right)$.

And if put this boundary condition we get, c_2 is equal to h^2 minus 1 by 8μ . I write 8 square by 8μ minus, this is a style of writing minus dp/dx , so c_2 becomes h^2 by 8μ minus dp/dx . So, if you substitute this c_2 here, finally you get the velocity profile like this, h^2 and $h\mu$ you take this as common, minus dp/dx into one minus $4y^2$ by h^2 . If we just put the value of c_2 here.

Then you get this equation and it can be written in a form like this which looks bigger, dp/dx into $1 - y^2$ by h^2 whole square. That means square of the hub height or hub

spacing of the channel. So, this is the u . Now it is clear from this equation that u is maximum. Now one thing, before that one thing you will see that if $\frac{dp}{dx}$ is zero, u is zero, unlike the Couette flow.

Because here the flow is driven by the pressure gradient and it is known as pressure driven flow. And it is at the same time apparent that the sign of $\frac{dp}{dx}$ and u are consistent. If we have any negative pressure gradient, that means pressure decreases in the positive direction of x which is known as favorable pressure gradient. That means the pressure force on a fluid element x in this direction, positive direction.

Pressure upstream is high, downstream is low and in that case u is positive. And accordingly, the reverse is true that $\frac{dp}{dx}$ is positive that when then downstream pressure is more than the off-stream pressure which we call as adverse pressure gradient when the pressure force on a fluid element these will be direction opposite to the positive direction of x . In that case this causes a velocity in the negative direction.

That means, flow is solely governed by the pressure variant and is known as pressure driven flow. Now the maximum velocity occurs at y is equal to zero and those value is, now it may be maximum minimum, the way you define it. If it is in the negative direction you call it a minimum and if it is a positive direction the $\frac{dp}{dx}$ negative you call it as a maximum. And accordingly, you see that $\frac{du}{dy}$, $\frac{d^2u}{dy^2}$ sign depends on $\frac{dp}{dx}$ on the first governing equation.

If $\frac{dp}{dx}$ is negative $\frac{d^2u}{dy^2}$ curvature as in that means velocity has been maximum and if $\frac{dp}{dx}$ is positive, $\frac{d^2u}{dy^2}$ is positive that means velocity has been minimum. So, it is a question of sign convention. But the value of u_{max} is this.

(Refer Slide Time: 09:55)

$$\begin{aligned}
 & \frac{h^2}{8\mu} \left(-\frac{dp}{dx} \right) \left(1 - \frac{4y^2}{h^2} \right) \\
 & \frac{h^2}{8\mu} \left(-\frac{dp}{dx} \right) \left[1 - \frac{y^2}{(h/2)^2} \right] \\
 & \frac{h^2}{8\mu} \left(-\frac{dp}{dx} \right)
 \end{aligned}
 \quad
 \begin{aligned}
 Q &= \int_{-h/2}^{h/2} u B dy \\
 &= \frac{h^3 B}{12\mu} \left(-\frac{dp}{dx} \right) \\
 Q &= \frac{h^3 B}{12\mu} \left| \frac{dp}{dx} \right|
 \end{aligned}$$

So sometimes we can write that u by U_{\max} this is another way of representing is one minus y square by h by 2 whole square. This is the velocity distribution. The next task is to find out the volumetric flow rate Q .

(Refer Slide Time: 10:26)

Now volumetric flow rate to find out, I have told you earlier that if I take a small element dy here and if you consider its width as b , a small element like this, cross sectional plane, that means if you see this view it is like this. This is dy and this is d . That means if we consider a small element of height dy and width d then through that the flow rate is u multiplied by $B dy$. That is the value of u prevailing at that particular y .

Now if you put this expression of view there and if you integrate to minus h by 2 to h by 2 that means across the channel high then you get a relationship like this, that is h cube B by 12

μ multiplied by dp/dx . That means you just substitute this μ and simply we integrate with y . This will be dy , this will be y^2 dy y^3 by 3 and accordingly you get this expression.

Now here one thing I like to mention very much which is not written in any book, I do not know that whether how many books have written it. Now volumetric flow rate is usually a scalar quantity. But if you deduce this way we come across with minus dp/dx . So, if you think of the sign of dp/dx because dp/dx is special value, it must have a sign. So dp/dx is either negative or positive.

That will indicate that pressure is increasing or decreasing in the direction of flow. So therefore, Q indicates a sign but it is better in my opinion to write Q as $h^3 B$ by 12μ , the absolute or mode value of dp/dx . I take only its value. And this represent a scalar quantity flow rate across the section.

(Refer Slide Time: 12:53)

$$\frac{u}{u_{max}} = 1 - \frac{y^2}{(h/2)^2} \quad u_{av} = \frac{Q}{A}$$

$$Q = \int_{-h/2}^{h/2} u B dy \quad u_{av} = \frac{h^2}{12\mu} \left| \frac{dp}{dx} \right|$$

$$= \frac{h^3 B}{12\mu} \left(-\frac{dp}{dx} \right) \quad u_{av} = \frac{2}{3} u_{max}$$

U average as average velocity in fluid flow is defined by the volumetric flow rate. That means for internal flow, flow through a duct, is defined as volumetric flow rate divided by the cross-sectional area. And if you do that cross-sectional area is B multiplied by h , then you get h^2 by 12μ mode of dp/dx . Of course, here you can put that minus dp/dx type of thing to show the direction of $U_{average}$ which will be inconsistent with the direction of U .

But if you think this way that average flow velocity I will consider as scalar quantity, it is a cross sectionally average based on the volume flow rate and which will simply represent the

value whether in the distribution Q , local velocity will have its sign accordingly with the sign of dp/dx . So therefore, you can keep this intact to show the U average as a scale of the Q , that is volumetric flow rate which is a scalar quantity.

So, it is simply h^2 by $12\mu dp/dx$. And if you see comparing with U_{max} then we can write that U average is two third of U_{max} , clear? Now the next task for us is to find out the shear stress at walls.

(Refer Slide Time: 14:45)

$$U_{av} = A$$

$$U_{av} = \frac{h^2}{12\mu} \left| \frac{dp}{dx} \right| (\tau)_{y=-h/2} = \frac{h}{2} \left(-\frac{dp}{dx} \right)$$

$$U_{av} = \frac{2}{3} U_{max}$$

$$(\tau)_{y=h/2} = \frac{h}{2} \left(\frac{dp}{dx} \right)$$

Now shear stress here takes place in the direction of x at any plane which is perpendicular to y whose normal is in the y direction. So, τ_{xy} from a general relation we know μ multiplied by shear rate or rate of angular or shear strain in xy plane, that is $\partial v / \partial x$ plus $\partial u / \partial y$, but at this moment, this is not necessary because we know everything here that there is no free component and U is a function of y only, du/dy .

So therefore, τ we can write, let us consider τ as y is equal to minus $h/2$. Now what is du/dy ? du/dy is this one. C_1 is zero, one by $\mu dp/dx$ multiplied by minus $h/2$. So therefore, it is one by μ . μ you divide, μ is cancelling each other, $h/2$ multiplied by $h/2$ into minus dp/dx . If you put this value y is equal to minus $h/2$. Now τ at the upper wall y is equal to $h/2$ is what, $h/2$ into dp/dx .

This is the value of shear stress at two walls. The numerical value is the same because of the symmetry, but about the sign you see one thing that here first let us consider a flow taking place in the positive direction U positive, then what is dp/dx , dp/dx is negative. So, if dp/dx is

negative, so τ at the lower plate is positive, that means in the x direction. Whereas τ at the upper plate is negative in the opposite direction true from this two equations.

(Refer Slide Time: 17:06)

But physically it is not so because the flow takes place in this direction, this is the flow direction. So, shear stress at the lower plate is acting in this direction and the shear stress on the upper plate should act also in this direction. So where is the problem, where is my confusion. This is because the coordinate, the upper plate implies that τ_{xy} is opposite to that. A positive τ_{xy} is in the opposite direction.

Because this is a plane where the normal is the negative y , not the positive y , I think this thing has been emphasized by Suman Chakraborty that when you specify the sign of a stress it is a second order tensor. So, it has two sign, one is this direction and another is the plane, specifying the direction, outward normal, but the outward normal is in the negative y direction and that is why the sign convention is there.

So, with this thing, now I will go to the most important parameter of any fluid flow analysis which engineers are mostly interested is the drag on the surface, solid surface, for external flow and for internal flow. For internal flow, it is most important because it is the shear stress at the solid surface that determines the pressure drop that already you have done your basic mechanics class

(Refer Slide Time: 18:35)

$$\begin{aligned}
 &= \mu \frac{du}{dy} \\
 &= \frac{h}{2} \left(-\frac{dp}{dx} \right) \\
 &= \frac{h}{2} \left(\frac{dp}{dx} \right) \\
 &= \frac{h}{2} \left(\frac{dp}{dx} \right)
 \end{aligned}
 \quad
 \begin{aligned}
 &\frac{1}{2} \rho U_{av}^2 \\
 &|\tau_w| = \frac{h}{2} \left| \frac{dp}{dx} \right| = \frac{h}{2} \frac{12\mu}{h^2} U_{av} \\
 &f = \frac{12}{Re} \quad Re = \frac{\rho U_{av} h}{\mu} \\
 &\downarrow \\
 &\text{Fanning Friction factor}
 \end{aligned}$$

So therefore, shear stress at the solid surface is very important and this defines a scalar quantity known as coefficient of friction c_f . I have already told earlier probably in one occasion that it is defined like this, half ρU average square, I already defined it earlier, so far if I recall that a friction coefficient in case of internal flow and drag coefficient in case of external flow is the representation of dimensionless wall shear stress or plate shear stress, surface shear stress which is defined as the shear stress, its absolute value.

Because this is a scalar quantity divided by the dynamic head based on the reference velocity which is U average in the present case. Present case means the internal flow it is the average velocity and for an external velocity it is the free stream time velocity. Now if we find out this one then you get τ_w is equal to $\frac{h}{2} \frac{dp}{dx}$. Now if you substitute that $\frac{dp}{dx}$ from the average velocity.

If you substitute $\frac{dp}{dx}$, $\frac{dp}{dx}$ mode from the average velocity then you get 12μ average velocity, it is equal to $\frac{h}{2} \frac{dp}{dx}$, that means 12μ by h^2 multiplied by U average. This is the, and if you substitute this, h will cancel and substitute d , you get an expression $\frac{12}{Re}$ by Reynolds number, where this Reynolds number is represented as ρU average h by μ . In any internal flow, the Reynolds number is defined based on the average velocity.

And hydraulic diameter which in this case is the height between the plates. This c_f is known as Fanning friction factor. This is all about the plane Poiseuille flow. It is very simple up to this. This is common. This is a generic equation, $C_1 y$ plus C_2 . From there the geometry of

the flow will allow. That means after this what happens is simply the algebra. There is no fluid mechanics.

And we have to understand the sign convention according to the algebra. Okay, clear?

(Refer Slide Time: 21:56)

Now we will discuss another situation of exact solution which is more important than plane Poiseuille and Couette flow in engineering practice is Hagen Poiseuille flow. Incidentally these two are the name of the two scientists Hagen and Poiseuille like Bose and Einstein, Bose Einstein theory. Bose Einstein is not a same person, two persons. So that people know since his or her work.

But this is fluid mechanics without thermo fluids people, people do not know Hagen and Poiseuille they are very famous top personnel, it is in the field. What is the Hagen and Poiseuille flow again, I am telling you it is a telling steady incompressible laminar fully developed flow through a cylindrical duct through a tube, through a pipe. That is why it is very common in engineering practice.

That means in a duct with a uniform circular cross section throughout. But the flow is fully developed. The growth of Boundary layer from the surface, merges at the axis and steady laminar incompressible, but the geometry is that it is a circular tube. Now if we analyze the flow through a tube, through a duct with circular cross section it is always convenient to use the cylindrical coordinate system. Cylindrical polar coordinate system.

And in cylindrical polar coordinate system, a point here is represented by 3 coordinates. One is the r , and the central line is considered to the line at r is equal to zero and to represent this point in a cylindrical polar coordinate system we have to see the cross-sectional view of this duct.

(Refer Slide Time: 24:28)

$\frac{\partial}{\partial \theta} (\text{any parameter}) = 0$
 $\frac{\partial V_z}{\partial z} = 0$ continuity Eqn.
 $\nabla \cdot \vec{V} = 0$
 $V_z = V_z(r)$

And if you see this cross sectional view it will be better that means this point comes here and this is our radial coordinate and with respect to any preferable direction this is the theta that you already know and z is the third-dimension perpendicular to this plane. That means in this view this is z . That means z is considered, some z is equal to zero plane, you consider this z , if z location is this. So that means r theta z is the coordinate of the point.

So, theta is the azimuthal coordinate, r is the radial and z is the axial coordinate. Now after specifying the coordinate system fluid mechanics stops here, only mathematics. Why? This is because this flow is a fully developed flow before that by the geometry of this flow it is axially symmetric or azimuthally symmetric. That means it is symmetric with respect to r is equal to zero which we call as an axi symmetric or azimuthal symmetric flow.

And this type of flow where the boundary conditions are also symmetric because around the entire cylindrical surface at values of r , it is a no slip condition, value u zero, that means it is azimuthally symmetric which can be mathematically written as $\frac{\partial}{\partial \theta}$ of any parameter is zero, of any parameter this comes fast from the definition of the problem, that means the problem is azimuthally symmetric for which r is equal to zero is taken as the central axis.

Next is the fully developed flow and this fully developed flow condition as you know that $\frac{\partial}{\partial z}$ is zero. That is the requirement of fully developed flow that z ceases to be a function of z . I have told earlier also it is function of r only. Because there is no dependence on θ . So therefore, the consequent is that v_z is a function of r only. Well, now let us write the continuity equation.

Let us write the continuity equation. Now continuity equation for an steady incompressible flow as you know the divergence of the velocity vector is zero.

(Refer Slide Time: 27:27)

The image shows a green chalkboard with handwritten notes. At the top, there is a diagram of a pipe with a cross-section labeled (r, θ, z) . A velocity vector \vec{V} is shown pointing in the z direction. The radial coordinate is labeled r and the axial coordinate is labeled z . The velocity component in the z direction is labeled V_z . To the right of the diagram, the following equations are written:

$$\frac{\partial}{\partial \theta} (\text{any param}) = 0$$

$$\frac{\partial V_z}{\partial z} = 0$$

$$V_z = V_z(r)$$

Below these equations, the divergence of the velocity vector is written as:

$$\nabla \cdot \vec{V} = \frac{1}{r} \frac{\partial}{\partial r} (r V_r) + \frac{1}{r} \frac{\partial}{\partial \theta} V_\theta + \frac{\partial}{\partial z} V_z$$

And the velocity vector is written as:

$$\vec{V} = V_r \vec{i} + V_\theta \vec{j} + V_z \vec{k}$$

And in a cylindrical coordinate system I write the divergence is as you know is $\nabla \cdot \vec{V}$, $\vec{i}, \vec{j}, \vec{k}$ if v_r, v_θ, v_z , now I have to define v_r . v_r is this, in the r direction. V_z is along v_z direction and v_θ is along the θ direction. So therefore, this is one up on $r \frac{\partial}{\partial r} v_r$ plus $\frac{1}{r} \frac{\partial}{\partial \theta} v_\theta$ plus $\frac{\partial}{\partial z} v_z$ and \vec{V} the velocity vector is defined as $v_r \vec{i} + v_\theta \vec{j} + v_z \vec{k}$ are the unit vector v_θ , sorry and $v_z \vec{k}$. Now this is a preliminary vector calculus.

(Refer Slide Time: 28:25)

$\frac{d}{d\theta}(\text{any parameter}) = 0$
 Continuity Eqn.
 $\frac{\partial V_z}{\partial z} = 0$
 $\nabla \cdot \vec{V} = 0$
 $V_z = V_z(r)$
 $\frac{1}{r} \frac{\partial}{\partial r} (r V_r) + \frac{1}{r} \frac{\partial V_\theta}{\partial \theta} + \frac{\partial V_z}{\partial z} = 0$
 $\frac{\partial V_\theta}{\partial \theta} = 0$
 $\frac{\partial}{\partial r} (r V_r) = 0$
 $V_z = 0$

This becomes one up on $r \frac{\partial}{\partial r} r V_r$ of $r V_z$, this has been told in your fluid mechanics class, $r V_r$ plus one up on $r \frac{\partial}{\partial \theta} V_\theta$ plus $\frac{\partial}{\partial z} r V_z$. That means it is counter part of $\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0$. So, this is the continuity equation. If we invoke the continuity equation this is zero because V_θ is absent.

The flow is defined with $V_\theta = 0$, there is no tangential component of velocity. It is not that only $\frac{\partial}{\partial \theta}$ of any parameter is zero but tangential component of velocity is absent. But both the cases that this time is zero. Then $\frac{\partial}{\partial z} r V_z$ by the definition of the fully developed flow zero.

So, we have then the only option that mean this equation tells this is zero which means that $\frac{\partial}{\partial r} r V_r$ is zero which means that, that $r V_r$, $\frac{\partial}{\partial r} r V_r$ or $r V_r$ exactly, that means $r V_r$ is zero, why? This is because similar we have obtained that $\frac{\partial}{\partial y} v = 0$ means $v = 0$ because impermeable boundary. So, if you apply this $r V_r$ from this point and go for each and every point in the flow you get the $r V_r$ zero. You understand me?

That means $\frac{\partial}{\partial y}$ of any, $\frac{\partial}{\partial y} v$ for example, $\frac{\partial}{\partial r}$ of any parameter is zero, means that parameter is zero provided this boundary condition stay, that two surfaces or along the surfaces this is zero. That means it will zero velocities in the entire field. So, this is a mathematical consequence and this has to be understood like that. If you put that condition at the surface, so you see that the immediate next point.

The immediate vicinity in that surface has to be zero if that gradient is zero, so that way next point is zero. So, it cannot initiate any value mathematically, it means that the field itself is zero. You understand? But if the surface, any one of the surface, here it is the single surface, but in case of two plates, the one of the surface is permeable there is a suction or blowing then this is not true.

That means even if this change with y is zero, the field is not zero. Clear to everybody? So, the similar way we obtain that $\frac{\partial v}{\partial y} = 0$, $v = 0$, $r \frac{\partial v}{\partial r} = 0$ means, next say the $r \frac{\partial v}{\partial r}$ is equal to zero except the singularity at the axis where r is equal to zero, that singularity I will show you how to tackle with the velocity distribution equation. So therefore, we get that $v_r = 0$, $v_\theta = 0$ and v_z is a function of r only.

Now you see that since $\frac{\partial p}{\partial \theta} = 0$ and there is no θ component of velocity, I do not want to invoke or call the Navier Stokes equation in θ direction. This is unnecessary. It is not required you can see in your book how it is written.

(Refer Slide Time: 32:20)

Now in our direction equation also, in absence of v_r and v_θ we will give you $\frac{\partial p}{\partial r}$, there cannot be a pressure gradient. If you expand because in this short time I do not want to write it. This remains as your task that probably it has been taught earlier that if you explain the Navier-Stokes equation in r direction, you will see in absence of v_r and v_θ that $\frac{\partial p}{\partial r}$ will be zero. It is similar to the Couette flow or plane Poiseuille flow in Cartesian coordinate $\frac{\partial p}{\partial y}$ is zero.

That means cross gradient is zero. And it is very easy to physically understand since there is no velocity in the r direction and no azimuthal velocity, no pressure gradient can exist. The question of azimuthal velocity comes because of the tangential velocity at radial pressure gradient is created which is responsible for the centripetal acceleration and the centripetal force.

So probably those had been taught at your fluid mechanics, basic fluid mechanics class. So therefore, in absence of v_r v_θ that there cannot be any radial pressure gradient. So, $\frac{\partial p}{\partial r}$ is zero and already parameter with respect to θ is zero, $\frac{\partial p}{\partial \theta}$ zero, we wrote it earlier the consequent, the speed becomes a function of z . It is in the similar lines we deal with the Cartesian coordinate system for plane Poiseuille and Couette flow.

Then I recall or invoke the r direction equation, Navier-Stokes equation. What is that? $\rho \frac{dv_r}{dt}$ is equal to minus $\frac{\partial p}{\partial r}$ plus μ of laplacian and v_r . Now I expand these for clarity, this temporal derivative though it is not required, you can tell sir we know that a steady flow temporal derivative is zero, however for the clarity then $v_r \frac{\partial v_r}{\partial r}$, plus one by r , rather $v_\theta \frac{\partial v_r}{\partial \theta}$, $\frac{\partial v_r}{\partial \theta}$ plus $v_z \frac{\partial v_r}{\partial z}$, equals to minus $\frac{\partial p}{\partial r}$ plus μ del square v_r .

Now if we split these I think it is better to write in a compact form like this, this again if you follow the vector algebra, with this notation of del in the cylindrical coordinate system it is again the vector algebra that $\nabla \cdot \nabla$, one by r , one by r if you write it is mathematics only, $\frac{\partial}{\partial r} \frac{\partial}{\partial r}$, $r \frac{\partial}{\partial r} \frac{\partial}{\partial r}$ plus one by r square, $\frac{\partial^2}{\partial \theta^2}$ plus $\frac{\partial^2}{\partial z^2}$ plus $\frac{\partial^2}{\partial r^2}$.

That means it is counter part of the laplacian in Cartesian coordinate, $\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$. So, it is the counter part of that, so it is in cylindrical polar coordinate system. Now, we know, first come here, this steady flow zero, we see how the z direction equation motion, the inertial term identically vanishes. v_r absent, v_θ absent.

And here though v_z is there but $\frac{\partial v_z}{\partial z}$ zero because of fully developed inertial term vanish. Now already this proof that v is a function of z , so it should be written in terms of ordinary differential equation and here also there is no dependence with θ for azimuthal

symmetry and there is no dependence with Δz square. There is no dependence with z . Δz square $v_z \Delta z$ square.

So only this term remains and also here I can replace this term as d , that means ordinary differential equation. That means from here, what I get, I get one by r , $d dr$ of $r d dz$ dr is equal to one by $\mu dp dz$. From this equation, I get this. I think it is okay, so that I can finally get from all three Navier-Stokes equation in 3 directions r θ z this equation. The $y-y$ obtained for Cartesian coordinate systems also for plane Poiseuille and Couette flow.

Now it becomes simple mathematics indication since v_z is a function of r and p is a function of z equally the whole goods for a constant, which means from here only the logic plays that p is a linear function of z then u is a quadratic function of r , so that equality holds good. They becomes constant. That is second derivative of $dz v$ with respect to r and first derivative of p with respect to z becomes constant. Now you integrate it.

The first integration was $d dr$ of this. That means $r d v_z$ equals to, you just multiply with r and integrate, that means r square by $2 \mu dp dz$ plus c_1 and then next one is $dv_z dr$ is r by $2 \mu dp dz$ plus c_1 by r and the next one is v_z is r square by $4 \mu dp dz$ plus $c_1 \ln r$ plus z .

(Refer Slide Time: 39:20)

$$\frac{1}{r} \frac{d}{dr} \left(r \frac{dv_z}{dr} \right) = \frac{1}{\mu} \frac{dp}{dz} = \text{constant}$$

$$r \frac{dv_z}{dr} = \frac{r^2}{2\mu} \frac{dp}{dz} + c_1$$

$$\frac{dv_z}{dr} = \frac{r}{2\mu} \frac{dp}{dz} + \frac{c_1}{r}$$

$$v_z = \frac{r^2}{4\mu} \frac{dp}{dz} + c_1 \ln r + c_2$$

B. Conditions:

at $r=R$ $v_z=0$

at $r=0$ $\frac{dv_z}{dr}=0$

$$c_2 = \frac{R^2}{4\mu} \left(-\frac{dp}{dz} \right)$$

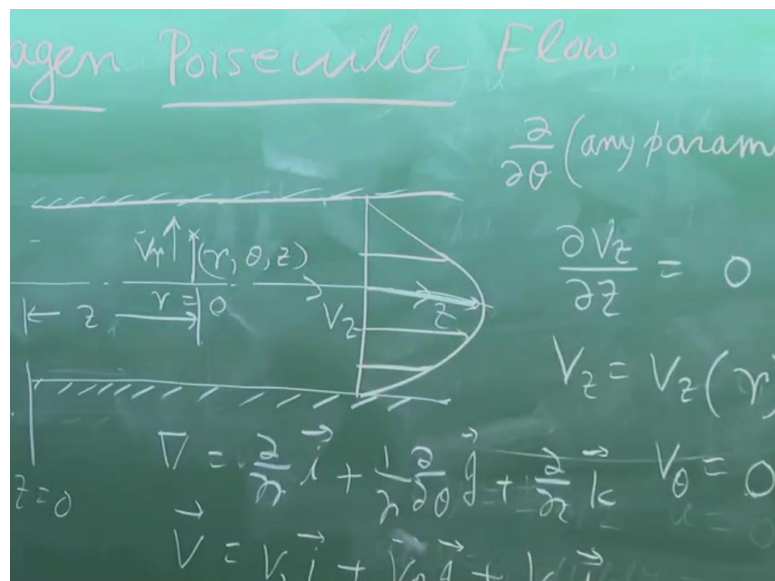

And here also the boundary conditions are at r is equal to r v_z zero. We have two constant. Another boundary condition is the azimuthal or axis symmetry condition which means $dv_z dr$ at r is equal to zero, rather you write in the same fashion, r is equal to zero, $dv_z dr$ is zero. Okay? And this automatically says that this equation cannot have a term like this, $\ln r$ is, that

is why I told that this will tackle the singularity at the center at r is equal to zero will be tackled automatically by allowing this c_1 to be zero.

So that this term vanishes and similarly in the $dv_z dr$ term, this term cannot happen to have this singularity. So therefore, this term will not come at all and this becomes symmetric about r is equal to zero and if you put that you will get c_2 is equal to R^2 by 4μ multiplied by minus dp/dz this is my technique of writing always minus dp/dz to show that plus minus should be associated with dp/dz .

We have an understanding with the favorable and the adverse pressure gradient depending up on the situation. Now after this our routine task is like this. We find out the maximum velocity. The maximum velocity at r is equal to zero obviously and that is equal to r square. Oh, I have not yet written this.

(Refer Slide Time: 41:20)

v_z then, if you substitute the c_2 here, then you get v_z r square, it is similar to Poiseuille thing 4μ multiplied by minus dp/dz multiplied by one minus r square by r square. The remaining part at school level thing, that v_z maximum that is v_z at r is equal to, at r is equal to zero that is r square by 8μ multiplied by minus dp/dz 4μ into minus dp , why I am writing 8μ , 4μ multiplied by minus dz .

So, one can explain v_z by v_z max as one minus r square by r square. So therefore, the Poiseuille flow like this. Similar is the Poiseuille flow, this is the distribution of velocity for various pressure gradient. So, minus dp/dz . So therefore, flow is purely driven by the pressure

gradient, pressure driven flow, where dp/dz is negative, flow is positive, dp/dz is positive, flow is negative, that means in the opposite direction. Next task is what?

(Refer Slide Time: 43:00)

$$\tau_{rz} = \left(-\frac{dp}{dz}\right) \left(1 - \frac{r^2}{R^2}\right)$$

$$r=0 \Rightarrow \tau_{rz} = 0 = \frac{R^2}{4\mu} \left(-\frac{dp}{dz}\right)$$

$$\mu \left(\frac{\partial v_z}{\partial r} + \frac{\partial v_r}{\partial z} \right)$$

Next task is τ_{rz} which is τ_{rz} . First of all, let us write τ . That means shear stress in the direction of flow which is in the rz plane. At any plane parallel to the flow that is rz plane which can be written as μ into corresponding rate of angular or shear strength, that is $\frac{\partial v_z}{\partial r}$ plus $\frac{\partial v_r}{\partial z}$. This has been taught at your basic fluid mechanics class, since in this case v_r is not there and v_z is a function of r .

Therefore, τ is $\mu \frac{dv_z}{dr}$. Well, therefore τ is $\mu \frac{dv_z}{dr}$. τ is $\mu \frac{dv_z}{dr}$.

(Refer Slide Time: 43:57)

$$\tau_{rz} = \frac{r}{2\mu} \left(\frac{dp}{dz}\right)$$

$$\tau_w = \tau_{rz} (at r=R)$$

$$\tau_w = \frac{R}{2} \left(\frac{dp}{dz}\right)$$

So therefore, τ_{rz} in this case is $\mu \frac{dv_z}{dr}$. Now rest part is very simple and routine. So, τ_w is nothing but τ_{rz} . Now let us find out τ_{rz} , $\mu \frac{dv_z}{dr}$. What is $\frac{dv_z}{dr}$? Now if you find out $\frac{dv_z}{dr}$ it will be, now let us find out this also. It is r , twice r square, r square is cancelling, r by 2μ multiplied by dp/dz . τ_{rz} is r by, that means you get $\frac{dv_z}{dr}$ from here. I have rubbed this, $\frac{dv_z}{dr}$ was there in the solution.

So $\frac{dv_z}{dr}$ if you may, then you will get this value that τ is equal to r by 2μ . You get $2r$, $2-2$ cancels and $2\mu r$ square, oh, also μ also will not be there, very good, r by $2 dp/dz$. There is no μ . Therefore, τ_w that means r by z , what is τ_w . τ_w is equal to τ_{rz} at r is equal to R . That becomes is equal to R by 2 multiplied by, here again the same understanding, that dp/dz negative gives a positive flow.

And shear stress physically acts in the positive direction but it gives a negative value mathematically because the plane is τ_{rz} negative because r is down one, very good. So similarly, if you write the friction coefficient as this, half $\rho \dots$ before that I have to find out v_z average. Sorry, I have not found out the v_z average, before that I have come to shear stress. Now let us find out average velocity or volumetric flow rate.

Volumetric flow rate again, volume average flow in case of a plane geometry, the volume average flow is simply the arithmetic average. But here the volume average flow to find out we have to consider an elemental area, annular area with thickness dr at a radius r , thickness dr which is represented here like this, this is the dr in this diagram which is an annular ring with widthness dr .

(Refer Slide Time: 47:10)

$$\begin{aligned}
 Q &= \int_0^R v_z(2\pi r) dr \\
 &= \frac{\pi R^4}{8\mu} \left(-\frac{dp}{dz} \right) \\
 Q &= \frac{\pi R^4}{8\mu} \left| \frac{dp}{dz} \right| \\
 v_{zav} &= \frac{R^2}{8\mu} \left| \frac{dp}{dz} \right| = \frac{v_{zmax}}{2}
 \end{aligned}$$

And to represent the q you can express this as the modulus of this. That means Q can be expressed as πR^4 by 8μ . I think this is more reasonable to understand because volume flow rate has no sign and v_z average therefore is equal to then divided by the cross-sectional area, that means R^2 by 8μ multiplied by dp/dz which is v_{zmax} by two. Now I come to the coefficient of friction.

(Refer Slide Time: 48:50)

$$\begin{aligned}
 C_f &= \frac{\tau_w}{\frac{1}{2} \rho v_{zav}^2} \\
 &= \frac{16}{Re} \\
 Re &= \frac{\rho v_{zav} (2R)}{\mu}
 \end{aligned}$$

The same way as I did earlier for plane Poiseuille flow if you define the coefficient of friction, C_f as τ_w by half ρv_z average square and if you use this τ_w v_z average from here, if you dp/dz , dp/dz if you, τ_w is r by $2 dp/dz$. So, if you substitute τ_w in terms of dp/dz and dp/dz in terms of the v_z average as I did earlier then it becomes equal to 16 by Reynolds number where Reynolds number in this case is defined as ρv_z average $2R$ by μ .

I do not want to spend time in such small school level calculations that I tell you that τ_w is R by two dp/dz . Here it is dp/dz , you can use the modulus of that, which will be again substituted in terms of v_z average, so that τ_w will come in terms of v_z average, ρ will be there and this thing is denominated ultimately. This will give, this is a Reynolds number defined on the basis of the diameter $2r$.

Diameter of the cylindrical duct which is the hydraulic diameter as you know it is defined as four cross sectional area divided by four times the cross-section area divided by the weighted perimeter and this comes out to be the diameter, $2r$ ρ average velocity. μ is the dynamic viscosity. So here I aim this discussion on Hagen Poiseuille flow but at the end I would like to tell you one thing, which I ignored from the beginning.

Whenever I write the Navier-Stokes equation it is $\frac{dp}{dx}$, $\frac{dp}{dy}$ or $\frac{dp}{dz}$. What is this p , you know, p is the piezoelectric pressures? So, I all books, in my book also you can see that people use p^* with a star. I think what Suman Chakraborty has told, when the Navier-Stokes equation is derived, we got rid of the body force balance. There is no body force we consider except gravity and we write the pressure gradient.

But gravity as the body force we can never neglect. We may neglect other body forces which are otherwise not imposed. Some electric field, some magnetic field may not be imposed on it. But gravity is there. So, gravity we never write as a body force, for example vertical flow in a vertical direction, y direction equation the gravity will come or in an inclined plane you have seen that liquid flowing gravity.

So that gravity is taken into account by piezoelectric pressure, this as we told it is a very preliminary knowledge at your basic fluid mechanics class. So, all this p what I have used, you consider this as a piezoelectric pressure. That is why in books usually it is written as p^* , if you see in many books, it is written and in my book also p^* .

(Refer Slide Time: 52:40)

$$\rho \frac{D\vec{V}}{Dt} = -\nabla p^* + \mu \nabla^2 \vec{V} + \frac{\mu}{3} \nabla (\nabla \cdot \vec{V})$$

$$p^* (\text{piezometric pressure}) = p + \rho g \frac{z}{g}$$

So, the pressure here which I write in the Navier-Stokes equation, for example if I write the Navier-Stokes equation, for example just this is for your concept, forget that exact solution is over, that when the Naviers-Stokes equation is written, let us write in a very compact vector from minus grad of p star, actually here we will not use star, we will read p as the piezoelectric pressure plus μ .

Forget about the next term, μ by 3 grad of that is not required, μ by 3 grad of $\nabla \cdot \vec{V}$. This is down for the comprehensibility. If incompressible flow, this is zero. But this p star is known as piezoelectric pressure. I think you know it takes care of the static pressure plus the gravity equivalent pressure. Not h , z where z is coordinate in the direction of gravity. It is elevation or whatever you get from a reference datum.

For example, when I told that the imposed pressure gradient, for an example like this, when this type of problem you have done earlier just for your concept I tell you.

(Refer Slide Time: 54:04)

For an example if there is an inclined plane and liquid plane is flowing and this plane is inclined by an angle θ . So, if you take a fluid element, pressure here is all atmospheric at this and this. If this is section one and this is section two, p_1 minus p_2 is zero, but then what causing the flow is the gravity, that means the component of its weight in this direction and that is the difference of the piezoelectric pressure force.

That means in that case the piezoelectric pressure difference p^* at one minus p^* at two will be $\rho g (z_1 - z_2)$. That time area, if you multiply our cross-sectional area you get the effective gravity. That means if you divide a cross sectional area A and if you define that this is z_1 and if you define here this is z_2 , then you will get this equation. That means if you define this as length, so the effective gravity that is $w \sin \theta$.

That means this is in this direction which is causing the element to come, liquid to flow and that is giving by this $\rho g (z_1 - z_2)$ into the cross-sectional area will be the pressure force. That means when we deal with this type of very simple equation at very fundamental stage at the basic stage preliminary stage of starting we do not think of that piezoelectric pressure will simply make the force balanced, that the gravity is fully in this.

And if the shear force in the liquid at the wall balances the effective gravity then the film flows with the constant or uniform velocity. So therefore, this gravity is taking in terms of a piezoelectric pressure where ρg the gravity prevalent pressure is there. So therefore, all these Navier-Stokes equation without any imposed body force from outside implies the pressure as the piezoelectric pressure.

When we deal with flows in horizontal plane, then the Δp is equal to Δp^* , that means the difference of piezoelectric pressure and difference that equation is same. So therefore, we can reduce, so that is simply static pressure So any questions? Alright. So, next class, we will start the Boundary layer theory, a brief introduction of the Boundary theory recapitulation like that. Many of you have already read it already in your fluid mechanics class, then that will be taken by the Prof. Suman Chakraborty. Okay. Thank you.
