Lecture - 22
Linear stability analysis- Cylindrical jet instability- 1

Good Morning. We will continue our discussion of linear instability analysis, and we will start by quickly recapping what we did in the last time.

(Refer Slide Time: 00:24)

We wrote down a series of steps that we go through; to start with an equilibrium solution, and then, we develop a linearized version of the governing equations about the equilibrium solution.

So what this does is it helps us understand, the behavior of a small perturbation around the equilibrium solution.

(Refer Slide Time: 02:58)

Now, if the equilibrium solution happens to be a constant, like the case that we discussed the dispersion relation can be obtained in closed form. If not one would have to solve for these eigenvalues, essentially the dispersion relation gives us the eigenvalues at any point in time. If the equilibrium solution is not a constant one would have to solve for those eigenvalues numerically. Say for example, you look at if the; I can apply the same exact methodology to look at the stability of the parabolic velocity profile in a round pipe.

When I take u equal to some 1 over r square over capital R square, which is like my parabolic velocity profile. It is not a constant in space essentially the mean the equilibrium solution is not a constant, therefore what we end up with is a forth order ordinary differential equation that and an eigenvalue problem, involving this forth order ordinary differential equation to which governs the growth or decay of the perturbation quantities. The forth order equation is very often called Orr sommerfeld equation.

So, essentially the Orr sommerfeld equation is a process is obtained through exactly the same process, except in that case you would have to solve for the eigenvalue with the largest real part, which is going to determine the growth of a given perturbation numerically. Whereas, in this case we are able to obtain it in closed form meaning: analytically, because the mean flow is simply a constant.

Now, I do not want to show that this is not something that is, that came out of the vim or fancy of a mathematician's mind, this process of obtaining the most unstable wave number.

(Refer Slide Time: 05:39)

Dispersion relation

$$\omega = f(k) \quad ; \quad \omega: \text{growth rate}$$

$$k: \text{wave number.}$$

$$\left. \frac{d\omega}{dk} \right|_{k=k_0} = 0$$

k_0 is the most destructive wavenumber

AIR: $U_1 = 10 \text{ ms}^{-1}$; $\rho_1 = 1.23 \text{ kg m}^{-3}$

WATER: $U_2 = 0 \text{ ms}^{-1}$; $\rho_2 = 1000 \text{ kg m}^{-3}$

So, essentially if we go back to this dispersion relation. It is some ω is a function of k ω is the growth rate, also in mathematical terms you would call that the eigenvalue, k is the wave number. This growth rate as a function of the wave number is some algebraic equation, in our case it turned out to be a polynomial, but in general it could be any algebraic equation explicit in some instances even implicit. But it still it is a closed form solution, that if I give you a k you can give me an ω , and it could be not 1 ω or 2 ω s, but many ω s, if ω happens to be a transcendental equation. If this equation happens to be a transcendental equation, but the 1 eigenvalue that I am interested in is the one with the largest real part, for that k it is that 1 eigenvalue that is going to govern the growth of that disturbance.

Now, so from this we can find at one particular value, I call this k_0 ; k_0 is the, what we would often call the most destructive wave number, which means that for a given disturbance of this wave number k_0 the growth rate ω the corresponding growth rate ω_0 is the maximum of all the possible growth rates for all the other wave

numbers. Which means, because of the functional form $\omega \propto k^3$ this particular wave number is going to cause, is going to appear to grow the fastest in relation to all other wave numbers.

So, and this has been and has been validated experimentally in many situations you know like the example that we just solved, you can show for yourself that when the water, you can go back to the dispersion relation that we solved. So, if you replace what we called fluid number 1 with air, and the fluid number 2 with water.

(Refer Slide Time: 08:51)

And also said σ to be equal to the surface tension of water, you will find that the λ_0 corresponding to k_0 is on the order of about 10 centimeters, 7 to 10 centimeters.

So, that is when air is blowing over a lake, that is otherwise at rest and air is blowing at the velocity of 10 meters per second, the repulse that we observe this theory predicts will be about 7 centimeters in wave length. This kind of a prediction can; obviously, be very easily validated in experiments and it has been validated; now what we want to do is look at how this theory can be applied to sprays and atomization which is what we are after now. So, if I take the first instance of an atomization problem, if I take a cylindrical

jet ensuing out of a nozzle of radius r , I am going to assume, so this is now the case of an axisymmetric flow.

I am going to assume ρ_1 and U_1 are the density and velocity of the fluid outside, ρ_2 and U_2 are the density and velocity of the fluid of the liquid itself. So, imagine just a water faucet, faucet through which a jet of diameter $2r$ is exiting into let us say air the air is at some velocity U_1 and the fluid is at some other velocity U_2 . Now what we do actually end up considering is not this problem, but the case of an infinite cylindrical jet. So, if I replace this with an idealized problem that is infinite in the z direction, I can go through the exact same process.

(Refer Slide Time: 13:04)

That is step one; write the governing equations, I leave the subscription notation i , like an our old notation, we said capital quantities are the mean flow quantities and in this case U_i happens to be a constant, U_1 and U_2 both are constant in their domain of definition.

So, if I now simplify this equation, $U \frac{dU_i}{dz}$ is 0 because, it is not a function of z and $\frac{dU_i}{dt}$ is also 0 which implies just like we found in the other case, $\frac{dU_i}{dz}$ well in this case I should write not x , but z because, what we can show from this. If I write the same equation in the r direction, what we find is that P_i is a constant except if you now, if you

remember in the flat interface problem we found that because, the interface curvature was 0 P_1 is also equal to P_2 . So, the pressure in both the fluids put together was a constant, we will see here that because you have this interface having a curvature.

So, if I this happens to be a round jet in cross section and the radius of that round jet is this capital R . So, what we find is that P_2 minus P_1 is equal to the σ over capital R . So, at the mean flow condition the capital P_2 , which is the pressure inside the liquid is constant inside the liquid P_1 is the pressure in the fluid outside that is in itself constant, but P_2 minus P_1 has to be equal to this σ over R , because of the surface tension pressure that occurs at the interface. Let us just make sure we understand this understand the physics of how this comes about, if I take a piece of that some $\Delta\theta$ in diameter in angle, if I take a piece of the jet and if P_1 happens to be the pressure P_2 happens to be the pressure here, and P_1 happens to be the pressure outside there is a surface tension force that acts at the cut section.

So, if I cut the fluid at some point here and here, there is a surface tension force that acts in either direction and this surface tension force as a component in this direction, and a component in this direction. What you will find is that this P_2 minus P_1 has to be sufficient to balance the normal component of these forces, the horizontal the vertical component as shown in this figure will cancel out, and from that you get this curvature dependence. So, if I take this angle the $\sin$ and the $\cos$ essentially, if I say that the normal component of this force which is this force is a function of this $\Delta\theta$. And therefore, you start to get these curvature effects, so if I take the perturbation quantities.

(Refer Slide Time: 19:04)

Handwritten notes on a digital whiteboard:

$$\vec{U} = \vec{U}_i + \vec{u}_i$$

Annotations for the velocity equation:

- $\vec{U}$: total velocity field
- $\vec{U}_i$: equilibrium velocity field
- $\vec{u}_i$: perturbation component

$$P = P_i + p_i$$

Linearized equations

From continuity, $\nabla \cdot \vec{u}_i = 0$

$$\frac{\partial \vec{u}_i}{\partial t} + U_i \frac{\partial \vec{u}_i}{\partial z} = -\frac{1}{\rho_i} \nabla p_i$$

If I write u as the $\bar{u}_i$ plus u_i vector, U is the total velocity field, U_i is the mean velocity field, mean or I would like to call it the equilibrium velocity field and this is my perturbation component. If I go through the same process that I went through before, and linearized these equations, I will keep these in the vector notation just too sort of make things a little easy for us, from continuity equation. What we find is that $\nabla \cdot \vec{u}_i = 0$ this says that the perturbation velocity field is also divergence free meaning the perturbation velocity field has to instantaneously obey this compressibility condition.

Essentially, $\nabla \cdot \vec{u}$ being 0 is coming from the fact that the fluid is incompressible and. So, if these are now the linearized equations that I am writing. I do not want to go through the same process of showing you how I substitute the mean plus perturbation into the full governing equations, take out all the order epsilon squared terms keep only the order epsilon terms, and that is when you get these linearized equations.

So, I am skipping those two steps, in the interest of time to just show you the equations that you get from this linearization, first equation is $\nabla \cdot \vec{u} = 0$ and the second equation. So, if I take the total pressure to be equal to this P_i plus little p_i just like we wrote in the previous case.

(Refer Slide Time: 22:19)

$$\nabla \cdot \vec{u}_i = 0 \quad \text{--- (1)}$$

$$\frac{\partial \vec{u}_i}{\partial t} + u_i \frac{\partial \vec{u}_i}{\partial z} = -\frac{1}{\rho_i} \nabla p_i \quad \text{--- (2)}$$

$\nabla \cdot (2)$ gives,

$$\frac{\partial (\nabla \cdot \vec{u}_i)}{\partial t} + u_i \frac{\partial (\nabla \cdot \vec{u}_i)}{\partial z} = -\frac{1}{\rho_i} \nabla \cdot (\nabla p_i)$$

$0 \text{ (eqn. 1)} \quad \quad \quad 0 \text{ (eqn. 1)}$

So, if I now take, I will mark these now as equations 1 and 2. If I take divergence of equation 2, and if I use equation 1 what we end up getting, is this equation $\nabla \cdot \nabla p_i$ the divergence of gradient of the pressure in each of the fluids is 0, which can also be written as $\nabla^2 p_i = 0$.

(Refer Slide Time: 24:04)

$$\nabla^2 \equiv \frac{1}{r} \frac{\partial}{\partial r} \left[r \frac{\partial}{\partial r} \right] + \frac{1}{r^2} \frac{\partial^2}{\partial \theta^2} + \frac{\partial^2}{\partial z^2}$$

$$\frac{1}{r} \frac{\partial}{\partial r} \left[r \frac{\partial p_i}{\partial r} \right] + \frac{1}{r^2} \frac{\partial^2 p_i}{\partial \theta^2} + \frac{\partial^2 p_i}{\partial z^2} = 0 \quad \text{--- (3)}$$

We said, $p_i(r, \theta, z, t) = \phi'_i(r) e^{(\omega t + ikz + im\theta)}$

Now, ∇^2 is a linear operator. So, I will just sort of write this out in a form, this is our equation that we get from just combining the system of linear equations that we have. Now I want to point out one thing here, the that will reinforce some of the concepts that we discussed in the earlier linear instability analysis, at this stage we introduce what we call the normal mode expansion, correct we said we will write p_i as $e^{i(\omega t + k z + m \theta)}$.

In previous case we did not have this $i m \theta$, in this case I am, I have two spatial variables over which the perturbation can vary, in the z direction as well as θ direction, we will see what this means in just a moment, but essentially I am assuming that my perturbation has two spatial variable forms, two spatial variables involved and one time variable. If I do that, I have this and of course, I have the pre multiplier this p_i is what we said would be the eigen function in the r direction. Now this is what we call the normal mode expansion, what I want to show you is that really speaking you do not even need to think of that as an assumption, the normal mode expansion is not an assumption that we make I show you how, if I look at equation 3.

(Refer Slide Time: 27:53)

Eq. (3) is the Laplace equation in 3 dim.

Say, $p_i(r, \theta, z, t) = R(r) \cdot \Theta(\theta) \cdot Z(z) \cdot T(t)$

$$\frac{1}{r} (r R')' \cdot \Theta Z T + R Z T \frac{\Theta''}{r^2} + R \Theta T \frac{Z''}{r^2} = 0$$

$\div$ by $R \Theta Z T$

$$\frac{1}{r} \frac{(r R')'}{R} + \frac{\Theta''}{r^2 \Theta} + \frac{Z''}{Z} = 0$$

So, we want to answer where does this come from, we in the previous analysis I showed this to you as though it was an assumption, but I want to show you that it is really not an

assumption, that there is fairly simple procedure to obtain it. So, if I look at equation 3 is the Laplace equation in three dimensions. So, this is in if I replace this p_i with capital T for temperature, that is standard heat conduction equation in three in cylindrical polar coordinates, steady state heat conduction equation in cylindrical polar coordinates, how would you solve that equation? You have to first identify which are the homogeneous directions and which is the direction in which you have may have some sort of an in homogeneity.

In this particular instance z is a coordinate in the vertical direction. So, the z coordinate basically is infinite, the θ coordinate is a periodic coordinate. So, clearly those are the two directions in which the coordinate as homogeneous boundary condition, homogeneous or periodic, really I should be say in periodic boundary conditions right. So, if I simply do a separation of variable solution on equation 3. So, if I say, p_i of r θ z and time is equal to r of r comma t times θ of θ comma t times z of z comma t . In fact, we do not even need the t in every one of this; I will show you in a moment that even that is not required, time sum capital T of t , if I take this assumption, which is essentially coming from separation of variables.

And I introduced that into the governing equation, what I will end up seeing here is. So, if I divide by capital R, I will write this first term also in this notation of in this prime notation indicating differentiation with respect to it is own argument. Now if I the standard procedure of solving you know three dimensional heat conduction equation, if I divide by R θ Z and T , what you end up seeing is this. Now if I non dimensionalize the r variable, using capital R then essentially what I have is that each of these terms is only of this term is only a function of Z this term is only a function of θ .

(Refer Slide Time: 33:42)

A screenshot of a digital notepad application showing a handwritten differential equation. The equation is:

$$\frac{1}{r} \frac{(rR')'}{R} + \frac{\Theta''}{r^2 \Theta} + \frac{Z''}{Z} = 0$$

Handwritten annotations include:

- $\div \text{by } R, \Theta, Z, T$ written above the equation.
- A yellow oval around the $\frac{\Theta''}{r^2 \Theta}$ term, with an arrow pointing to it labeled $\theta(\theta)$.
- A yellow oval around the $\frac{Z''}{Z}$ term, with an arrow pointing to it labeled $f(z)$.
- The term r^2 is written above the Θ term.
- The term $= 0$ is written to the right of the equation.

And if the sum of three functions, that are each of a particular independent variable have to all add up to 0 the only way they can add up to 0 is if we each of them as a constant.

(Refer Slide Time: 34:15)

A screenshot of a digital notepad application showing handwritten equations for separation of variables. The equations are:

$$\frac{Z''}{Z} = -k^2 ; \frac{\Theta''}{\Theta} = -m^2$$

$$Z(z) = e^{ikz} ; \Theta(\theta) = e^{im\theta}$$

Below these, it says "Sub. eqn. (4) into eqn. (3),". Then the following equation is written and labeled (5):

$$\frac{1}{r} \frac{\partial}{\partial r} \left[r \frac{\partial p'}{\partial r} \right] - \frac{m^2}{r^2} p' - k^2 p' = 0 \quad \text{--- (5)}$$

Below this, another version of the equation is written:

$$\frac{1}{r} \frac{d}{dr} \left[r \frac{dp'}{dr} \right] - \frac{m^2}{r^2} p' - k^2 p' = 0$$

The standard solution by separation of variables, so from there you get the equation that Z del equals minus k squared, if I say θ double prime over θ equals. So, minus m

square and I get do this by separating out the r part. So, if this part is equal to some minus k squared, then the solution for this. So, essentially if I start out so the assumption of periodicity in the z direction and θ direction comes from taking the system of equations that we have which is an equation 1 and 2 eliminating some of the unknowns in favor of the others.

So, like for example, in this case I eliminated U i vector, which is u v w velocities in favor of p . So, I end up getting one homogeneous equation in terms of the pressure and after I have that, which have written out in form as equation 3 identifying which are the periodic directions. Once I identify which are the periodic directions, I can then solve this as though I am solving this problem by separation of variables, and this is and what I end up with is what we call the normal mode assumption in the past in the last class. So, essentially in a mathematically this is a Sturm Liouville problem that yields orthogonal eigen functions in k in the z direction, and orthogonal eigen functions in the θ direction and essentially this normal mode assumption is just coming from the fact that after eliminating these equations you get a Sturm-Liouville problem.

So, now let us just, so it comes from the fact that we are dealing with a Sturm Liouville problem. This is the answer in the previous case it was a Sturm Liouville problem in two dimensions x and y , if we did this in the previous case we would have simply gotten $\nabla^2 p = 0$, and there $\nabla^2 p$ would have simply been the partial derivative of p with respect to x twice, partial secondary derivative plus $\nabla^2 p = \frac{\partial^2 p}{\partial x^2} + \frac{\partial^2 p}{\partial y^2} = 0$. So, you just have been $\nabla^2 p = \frac{\partial^2 p}{\partial x^2} + \frac{\partial^2 p}{\partial y^2} = 0$, you identify that x is the periodic direction in that problem y happens to be the depth direction.

So, it is not the periodic direction and so, you get $\sin$ function e^{ikx} in the x direction, and corresponding to each e^{ikx} you get either e^{-ky} or e^{ky} depending on which ever the two fluids, you are in the standard solution to Laplace equation in two dimensions. So now, let us take this forward if I take this normal mode assumption of the form four and substitute into three, what do I get? Now p' is only a function of r full building, this p' we said is a function of r and. So, essentially this equation will call this equation five really should be written as an

ordinary differential equation. So, just to be precise is an ordinary differential equation in p prime.

(Refer Slide Time: 40:12)

As it turns out this is called the Modified Bessel Equation, and the solutions of this are the general solution.

This C_{11} and C_{12} are actually four constants we have seen C_{11} for i equal to 1 and i equal to 2, C_{11} , C_{12} , C_{21} , and C_{22} . Now when i equal to 1 what we do want to know is that the solution is bounded inside i equal to 1. So, just to be clear i equal to 1 is the outside fluid, the graph of $I_m(kr)$ for i as a function of x , looks something like this for different values of m this happens to be m equal to 0 and this is qualitatively how any m greater than 0 looks. So, as r becomes large kr becomes large and I_m of kr increases indefinitely as r becomes large. So, all we know is that C_{11} has to be equal to 0, it is coming from the solution not just being bounded, but the solution leading to disappear towards 0.

Likewise when i equal to 2, this happens to be the case with the inside fluid now we use the fact that the solution has to be bounded inside the liquid jet inside the fluid.

(Refer Slide Time: 43:41)

So, just to be clear if I draw graph of K_m of x as a function of x , this is a functional form. So, as x becomes smaller and smaller the value of K_m of x becomes larger and larger this is called the K_m is called the modified Bessel function of the second kind, and I_m is the modified Bessel function of first kind.

So, I_m has this kind of a property K_m has this kind of a property, so when m is equal to 2 if K_m of r happens to as r becomes small K_m of r becomes unbounded, which means that C_{22} has to be equal to 0. So, from here I can write the full pressure in the outside fluid now once I find p_1 and p_2 , what I also know is that U_i has to be composed of the same normal modes as p_i .

(Refer Slide Time: 46:45)

u_i has to be composed of the same normal modes as p_i .

$$\left(\frac{\partial}{\partial t} + U_i \frac{\partial}{\partial z} \right) u_i = -\frac{1}{p_i} \nabla p_i$$

So, if I you can this is again this is also not an assumption, I can go back to the original equation number 2 which said d/dt .

So, if I take the solution for p_i that I have substitute in this equation essentially take the gradient of p_i and said term wise, how these have the parts of U_i corresponding to time and spatial variation have to equal, you end up getting exactly this. So, this is a characteristic of any linear problem that the response of the linear system is always the same as the response in the forcing function. So, what we want to do is use that fact. So, U_i is also is also of the same functional form in r θ z and time.

(Refer Slide Time: 47:49)

$\eta: \eta_0 \exp(\omega t + ikz + im\theta)$
 Kinematic boundary condition,
 $\left(\frac{\partial}{\partial t} + U_i \frac{\partial}{\partial z}\right) \eta = \underbrace{\vec{u}_i \cdot \hat{e}_r}_{\text{radial component of velocity}},$
 Dynamic boundary condition.

Now so essentially that gives us an analytical solution for all of U_i and p_i and then finally, like we said we have two sets of boundary conditions, one is called the kinematic boundary condition, that says $d/dt + U_i d/dz$ acting on the interface is equal to $U_i \cdot e_r$ this is my way of saying that this is the radial component of velocity that I am concerned about on this side, also η is some perturbation just like of the same exact form has the one we have before.

(Refer Slide Time: 49:51)

$\left(\frac{\partial}{\partial t} + U_i \frac{\partial}{\partial z}\right) \eta = \underbrace{\vec{u}_i \cdot \hat{e}_r}_{\text{radial component of velocity}},$
 Dynamic boundary condition,
 $p_2 - p_1 = \sigma \left(\frac{1}{R_1} + \frac{1}{R_2} \right); R_{1,2} \text{ : Principal Radii of Curvature}$

And then we have the dynamic boundary condition, p_2 minus p_1 now these are the differences in the perturbation pressures alone, and these are functions of the principal radii of curvature.

We will continue with this discussion in the next class, where we will start from here and work our way to the dispersion relation for a cylindrical jet.
