Lecture - 23
Microprocessor

I welcome you all to today's NPTEL online certification course on Mechatronics. Today we are going to talk about Microprocessors. Here if you look at this chart on the different mechatronic system components, the microprocessor falls into this category that is under the digital control architecture.

(Refer Slide Time: 00:56)

So, in this lecture and next lecture, I am going to talk about microprocessors and microcontrollers. So, as we have seen in the last class, that is on combinational and sequential logic IC's. So, if you have a simple control problem, then that can be solved using combinational and sequential logic IC's, that is, integrated circuits.

(Refer Slide Time: 01:33)

Introduction

- Simple control problem, can be solved by an electronic control system using combinational and sequential logic integrated circuits.
- However, with complex situation there might be many more variables to control in a more complex control sequence.
- With combinational and sequential logic IC wired connections are used to connect.
- For complex situations microprocessor are used and software is used to make the interconnections.

But if you have a complex problem where we are going to have many more variables to control, and there is a more complex control sequence in such type of situation, combinational and sequential logic IC wired connections might not be very useful. So, for such complex situations, microprocessors are used, and software is used to make the interconnections.

(Refer Slide Time: 02:17)

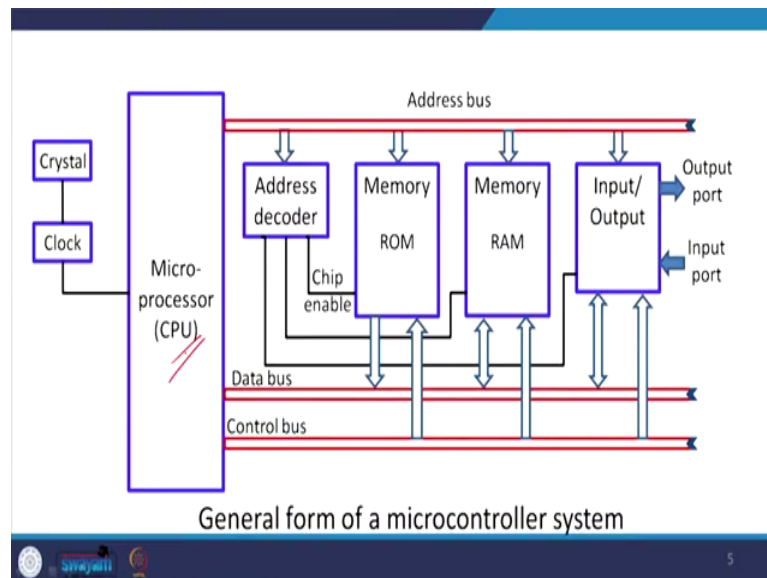

Microprocessor System ✓

- Microprocessor system has three parts namely Central Processing Unit (CPU), Input & Output interfaces and Memory
- CPU recognise and carry out program instructions (this part of microprocessor system uses the microprocessor)
- I/P & O/P interfaces handle communications between the microprocessor and the outside world
- Memory hold the program instructions and data
- Microprocessor having memory, input & output arrangements all on same chip are **microcontrollers**

Let us look at the microprocessor system. A microprocessor system has essentially got three main parts. These are the central processing unit, which we call in short CPU, input and output interfaces for interacting with the microprocessor, and a memory. So, these three are the principal components of a microprocessor system.

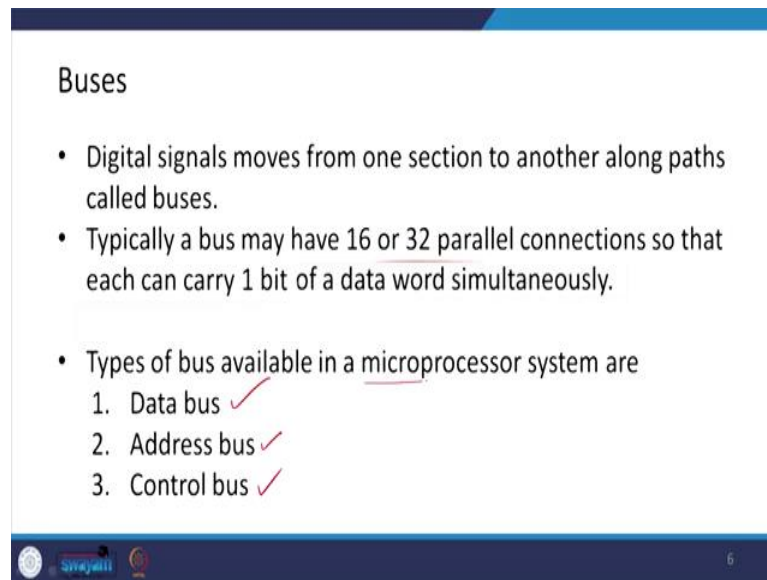

The central processing unit recognizes and carries out the program instructions, and this part of the microprocessor system uses the microprocessor. So, in a microprocessor system, the CPU is the component that uses the microprocessor, and here it carries out the program instructions. Then next is the input and output interfaces, and these handle communication between the microprocessor and the outside world. They receive inputs as well as they give the output. The microprocessor receives input and gives the output through with the help of these interfaces. The memory, as the name indicates, holds the program instructions as well as data. So, it will store the program instructions and the data. Microprocessors have memory input-output arrangement, all on the same chip that is what is called the microcontrollers, and this I am going to discuss in detail in my next lecture.

(Refer Slide Time: 04:26)

So, let us look at the general form of a microcontroller system or the microprocessor system, where we have a microprocessor or what is we call a CPU that is a CPU that uses a microprocessor. We have crystal and clock, and then as I was telling you, we have the input and output. So, we have an input-output unit is there. So, you have an input port, output port, and then these are the memories. So, memory is there. I am going to talk about these memories a little later in this lecture. And then, there are different buses; address bus, data bus, and control bus. And what do you mean by this bus, again I am going to discuss this in the next slide.

(Refer Slide Time: 05:18)

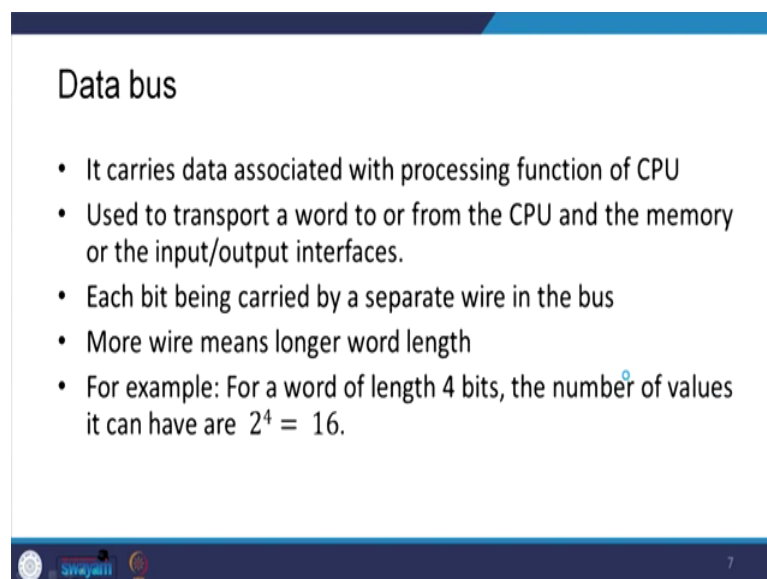

The slide is titled "Buses" and contains a bulleted list. The first bullet point states that digital signals move from one section to another along paths called buses. The second bullet point notes that a bus typically has 16 or 32 parallel connections, each carrying 1 bit of a data word simultaneously. The third bullet point lists the types of buses available in a microprocessor system: Data bus, Address bus, and Control bus, each with a red checkmark next to it. The slide footer includes a logo, the name "Sriyaji", and the number "6".

Buses

- Digital signals moves from one section to another along paths called buses.
- Typically a bus may have 16 or 32 parallel connections so that each can carry 1 bit of a data word simultaneously.
- Types of bus available in a microprocessor system are
 1. Data bus ✓
 2. Address bus ✓
 3. Control bus ✓

The digital signal moves from one section to another along paths, and these paths we are calling as a bus. Typically a bus may have 16 or 32 parallel connections so that each can carry 1 bit. So, you can have the 16 bit or 32 bit like that. So, they can carry 1 bit of data word simultaneously. The type of bus, as we have seen here, is the address bus, data bus, and control bus. So, these are the types of the bus that are available in a microprocessor system.

(Refer Slide Time: 06:10)

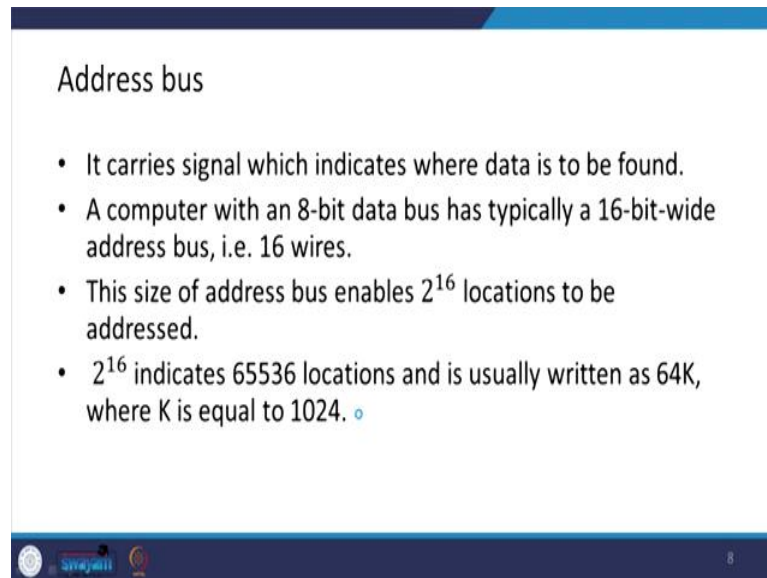

The slide is titled "Data bus" and contains a bulleted list. The first bullet point states that it carries data associated with the processing function of the CPU. The second bullet point notes that it is used to transport a word to or from the CPU and the memory or the input/output interfaces. The third bullet point states that each bit is carried by a separate wire in the bus. The fourth bullet point notes that more wires mean a longer word length. The fifth bullet point provides an example: for a word of length 4 bits, the number of values it can have are $2^4 = 16$. The slide footer includes a logo, the name "Sriyaji", and the number "7".

Data bus

- It carries data associated with processing function of CPU
- Used to transport a word to or from the CPU and the memory or the input/output interfaces.
- Each bit being carried by a separate wire in the bus
- More wire means longer word length
- For example: For a word of length 4 bits, the number of values it can have are $2^4 = 16$.

Let us look at what do these buses do. The data bus carries data associated with the processing function of a CPU. It is used to transport a word to and from CPU and memory or the input-output interfaces. Each bit is carried by a separate wire in the bus, and more wire means longer is the word length, so as it indicates. So, for example, for a word of length 4 bit, the number of values it can have is 2^4 that is 16.

(Refer Slide Time: 06:57)

Address bus

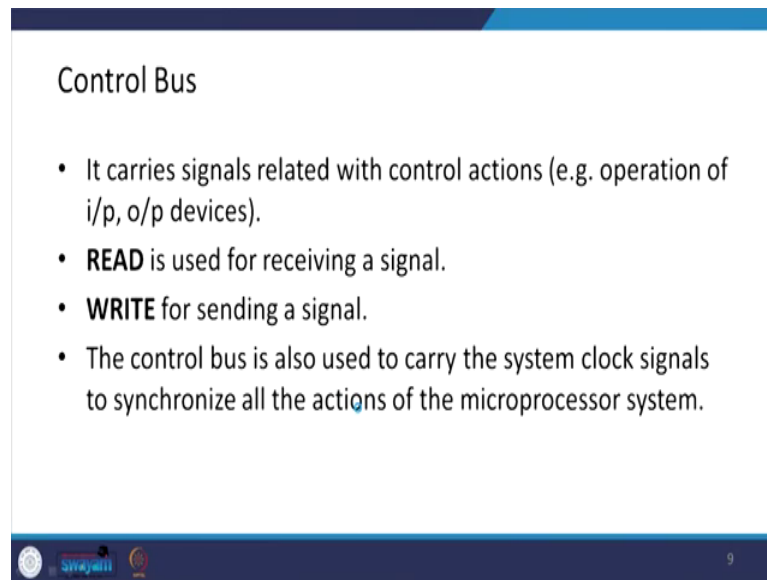

- It carries signal which indicates where data is to be found.
- A computer with an 8-bit data bus has typically a 16-bit-wide address bus, i.e. 16 wires.
- This size of address bus enables 2^{16} locations to be addressed.
- 2^{16} indicates 65536 locations and is usually written as 64K, where K is equal to 1024. ◦

Next, let us look at the address bus. So, as the name indicates, it carries a signal which indicates where data is to be found; so some sort of address of the data. So, a computer with an 8-bit data bus typically has a 16-bit wide address bus that is the 16 wires. The size of the address bus enables 2^{16} locations to be addressed, and it indicates 65536 locations and is usually written as 64 K, where K is equal to 1024.

(Refer Slide Time: 07:49)

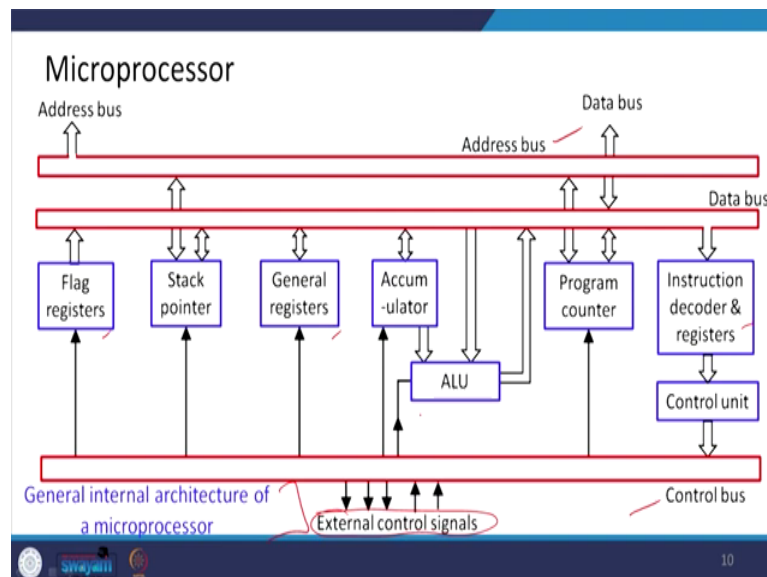

Control Bus

- It carries signals related with control actions (e.g. operation of i/p, o/p devices).
- **READ** is used for receiving a signal.
- **WRITE** for sending a signal.
- The control bus is also used to carry the system clock signals to synchronize all the actions of the microprocessor system.

Next is the control bus, which carries a signal related to the control action; that is, the operation of the input-output devices. READ is used for receiving a signal, whereas WRITE is used for sending a signal. The control bus is also used to carry the system clock signals to synchronize all the actions of the microprocessor system.

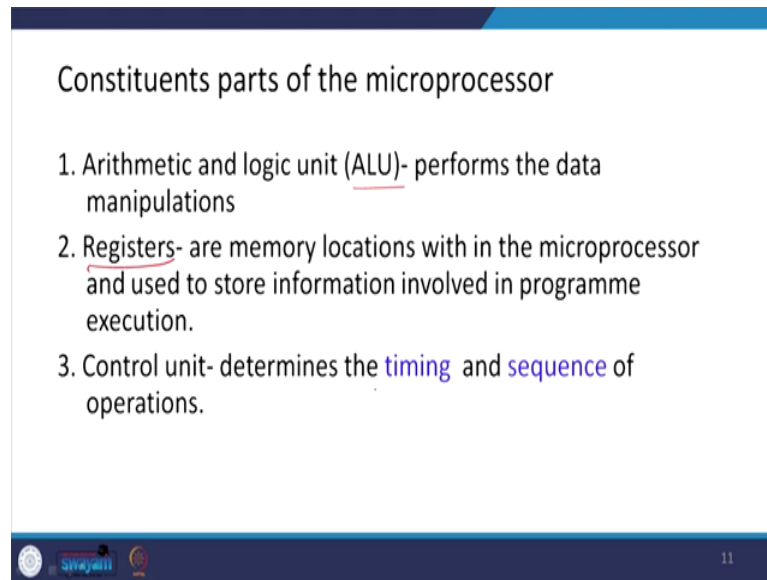

(Refer Slide Time: 08:21)

So, if we look at the microprocessor here, so, as I was telling you, we have the address bus, data bus, and the control bus. Also, the three buses are indicated by the red over here. And we have different registers here flag register, general register. I am going to talk about

what these are instruction and instruction decoder and register. Then you have an accumulator which is connected to the or which communicates through ALU, that is, arithmetic logic unit. So, this is the general internal architecture of a microprocessor, and from here, they get external control signals; so in come and in as well as out.

(Refer Slide Time: 09:15)

The constituent part of the microprocessor, as I said ALU, that is, arithmetic and logic units perform the data manipulation. The ALU, which performs the data manipulation. Then there are different registers, as I said, and these are memory locations within the microprocessor and used to store information involved in program execution. And the control unit determines the timing and sequence of the operation.

(Refer Slide Time: 09:53)

Registers

1. Accumulator register- temporary holding register for data to be operated on by ALU and after operation holds the results.
2. Status register/flag register-
 - carries information concerning the results of the latest process carried out in ALU.
 - It carries individual bits called flags.
 - Used to indicate whether the last operation resulted in a negative result, a zero result, a carry output occurs, an overflow occurs or the program is allowed to be interrupted.

Now, let us look at the different types of registers. So, we have the accumulator register, and this temporary holding register for data to be operated on by ALU and after operation holds the results. Then we have the status or flag register. So, as the name indicates, it carries information concerning the results of the latest process carried out in the ALU. It carries individual bits, which we call flags, and it is used to indicate whether the last operation resulted in a negative result, a zero result, or a carry output occurs, and overflow occurs, or the program is allowed to be interrupted. So, this is all information it has.

(Refer Slide Time: 10:54)

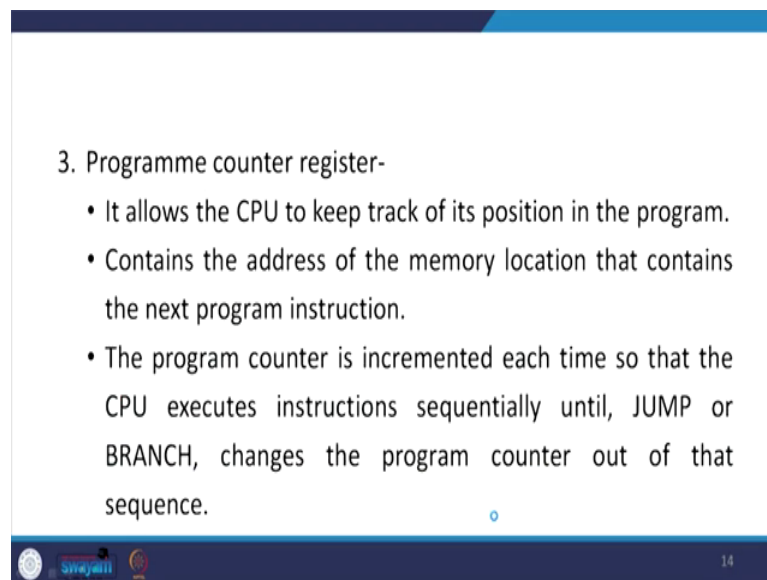

- Common flags in status register

Flag	Set, i.e. 1	Reset, i.e. 0
Z	Result is zero ✓	Result is not zero
N	Result is negative ✓	Result is not negative -
C	Carry is generated ✓	Carry is not ignored -
V	Overflow occurs ✓	Overflow does not occur -
I	Interrupt is ignored ✓	Interrupt is processed normally ✓

There are common flags in the status register. For example, the flag Z set 1; set that is 1 and reset that is represented by 0. So, Z, if the result is zero, it is represented by 1, and if

the result is not zero, it is represented by 0. Similarly, you have N result is negative, the result is non-negative. C carry is generated; here, carry is not generated. And V overflow occurs, overflow does not occur over here and interrupts are ignored, and interrupt is processed normally. So, these are the different flags in the status register.

(Refer Slide Time: 11:49)

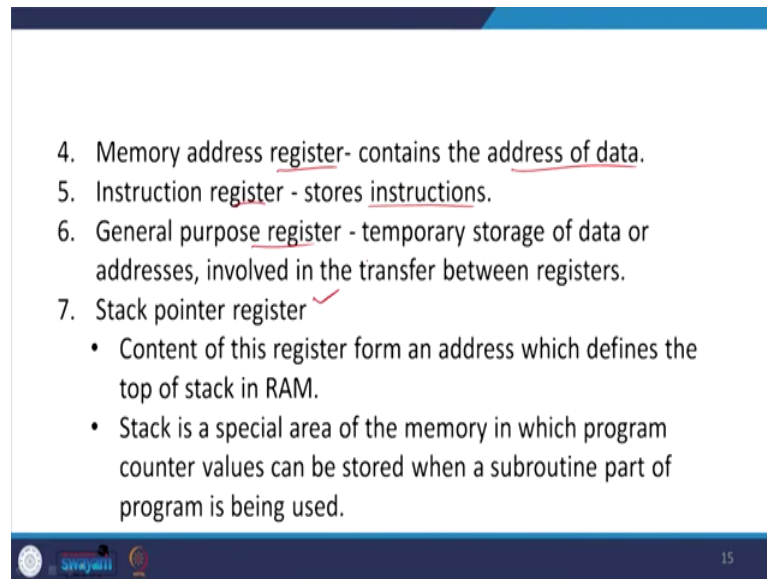

3. Programme counter register-

- It allows the CPU to keep track of its position in the program.
- Contains the address of the memory location that contains the next program instruction.
- The program counter is incremented each time so that the CPU executes instructions sequentially until, JUMP or BRANCH, changes the program counter out of that sequence.

Next is the program counter register. It allows the CPU to keep track of its position in the program. It contains the address of the memory location that contains the next program instruction. The program counter is incremented each time so that the CPU executes instructions sequentially until JUMP or BRANCH changes the program counter out of that particular sequence. Then we have the memory address register, which contains the address of data. We have an instruction register that stores instructions. We have the general-purpose register, and these are temporary storage of data or addresses involved in that transfer between registers.

(Refer Slide Time: 12:45)

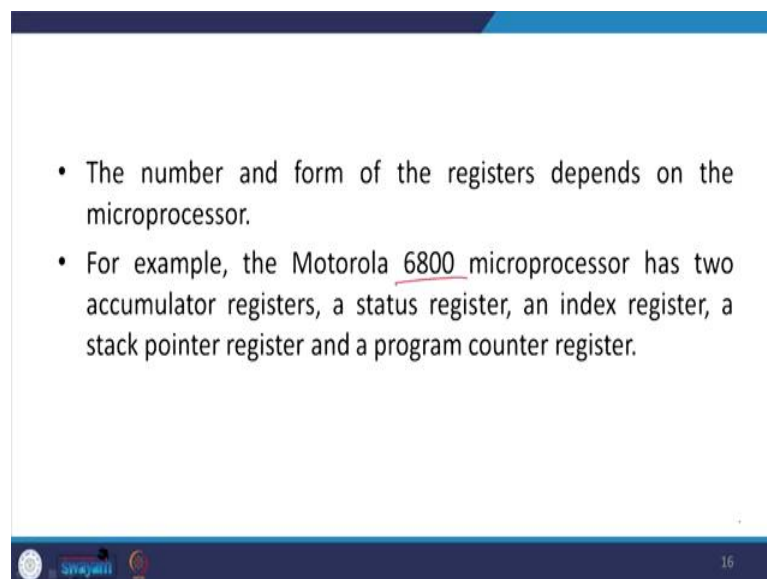

Slide 15 contains a list of register types:

4. Memory address register- contains the address of data.
5. Instruction register - stores instructions.
6. General purpose register - temporary storage of data or addresses, involved in the transfer between registers.
7. Stack pointer register ✓
 - Content of this register form an address which defines the top of stack in RAM.
 - Stack is a special area of the memory in which program counter values can be stored when a subroutine part of program is being used.

The slide footer includes a logo, the text 'Swayam', and the number '15'.

And we have a stack pointer register. The content of this register forms an address that defines the top of the stack in the RAM. And stack is a special area of the memory in which program counter values can be stored when a subroutine part of the program is being used.

(Refer Slide Time: 13:10)

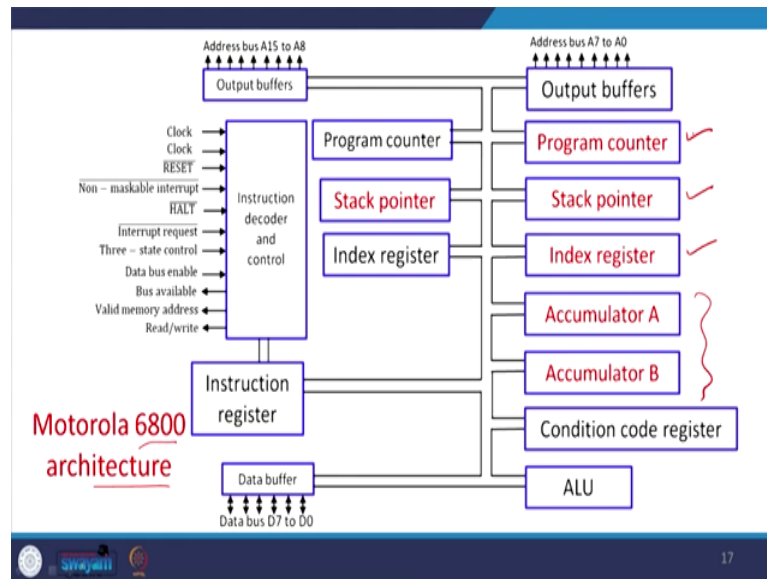

Slide 16 contains a list of register characteristics:

- The number and form of the registers depends on the microprocessor.
- For example, the Motorola 6800 microprocessor has two accumulator registers, a status register, an index register, a stack pointer register and a program counter register.

The slide footer includes a logo, the text 'Swayam', and the number '16'.

The number and the form of the register depend on the microprocessor. For example, Motorola 6800 microprocessor has two accumulator registers, a status register, an index register, a stack pointer register, and a program counter register.

(Refer Slide Time: 13:29)

Next slide, I am showing here Motorola 6800 architecture. So, as I said, it has got two accumulators; accumulators A and B. It has an index register, a stack pointer, and a program counter are there. It also has an output buffer, ALU, condition code register, instruction register, instruction decode, and control, and here you have the various pins for the different types of addresses; clock, RESET and all.

Then let us look at the memory. The memory units store binary data, and the size of memory is determined by the number of wires in the address bus; based on that, the size of memory is found.

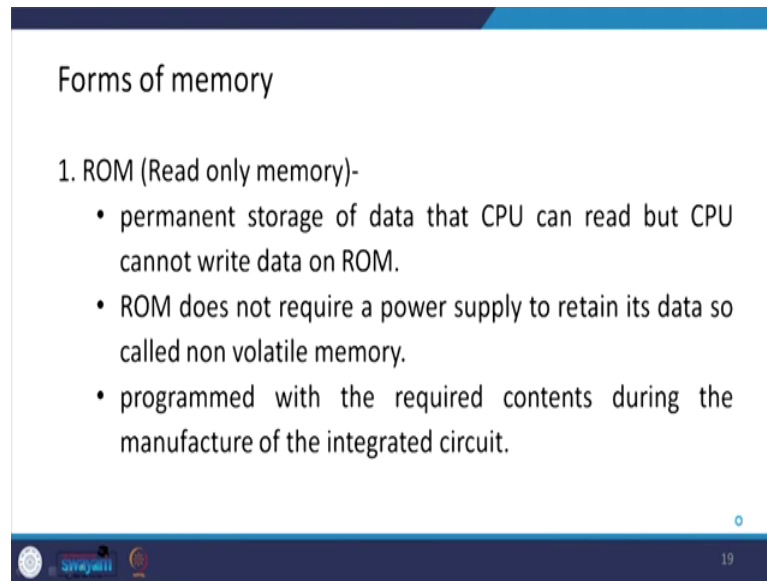

(Refer Slide Time: 14:33)

Memory

- Memory units store binary data.
- Size of memory determined by the number of wires in the address bus.
- Memory unit consists of large number of storage cells with each cell capable of storing 0 or 1 bit.
- Storage cells grouped into a location with each location storing a word.
- In order to access the stored word each location is identified by a unique word.
- Size of memory specified in terms of no. of memory locations available. 1 K is $2^{10} = 1024$ (4K memory has 4096 locations.)

Memory units consist of a large number of storage cells, with each cell capable of storing 0 or 1-bit storage cells grouped into a location, with each location storing a word. And in order to access the stored word, each location is identified by a unique word. And the size of memory is specified in terms of the number of memory locations available. So, 1 K is 2^{10} or 1024. So, and 4 K memory has that is 4096 locations.

(Refer Slide Time: 15:12)

The slide is titled "Forms of memory" and lists the characteristics of ROM (Read Only Memory). It includes a list of three bullet points: permanent storage of data that CPU can read but cannot write on, non-volatility (no power supply needed), and pre-programming during manufacturing. The slide footer contains logos for Swayam and the number 19.

Forms of memory

1. ROM (Read only memory)-
 - permanent storage of data that CPU can read but CPU cannot write data on ROM.
 - ROM does not require a power supply to retain its data so called non volatile memory.
 - programmed with the required contents during the manufacture of the integrated circuit.

Now, let us look at the forms of memory. First of all, we will see the ROM that is what we call the read-only memory. Now, as the name indicates, it is read-only memory. So, it is permanent storage of data that the CPU can read; but the CPU cannot write data on ROM because it is a read-only memory. It is a read-only memory that does not require a power supply to retain its data, so it is called non-volatile memory. And this is programmed with the required content during the manufacture of the integrated circuit or the IC's.

(Refer Slide Time: 16:02)

2. RAM (Random access memory)-

- can be read from or written to at any time provided power is there.
- Data is considered volatile because it is lost when power goes.
- Static RAM- retains data in flip flop as long as memory is powered.
- Dynamic RAM-consists of capacitor storage of data that must be refreshed (rewritten) periodically because of the charge leakage.

20

Next is the RAM, which is called random access memory. This can be read from or written to at any time provided power is there, and data is considered volatile because it is lost when the power goes. So, again the RAM is of 2 types; that is static RAM and dynamic RAM. The static RAM retains data in a flip flop as long as memory is powered, and the dynamic RAM consists of capacitor storage of data that must be refreshed or rewritten periodically because of the charge leakage.

(Refer Slide Time: 16:42)

3. EPROM (Erasable programmable ROM)-

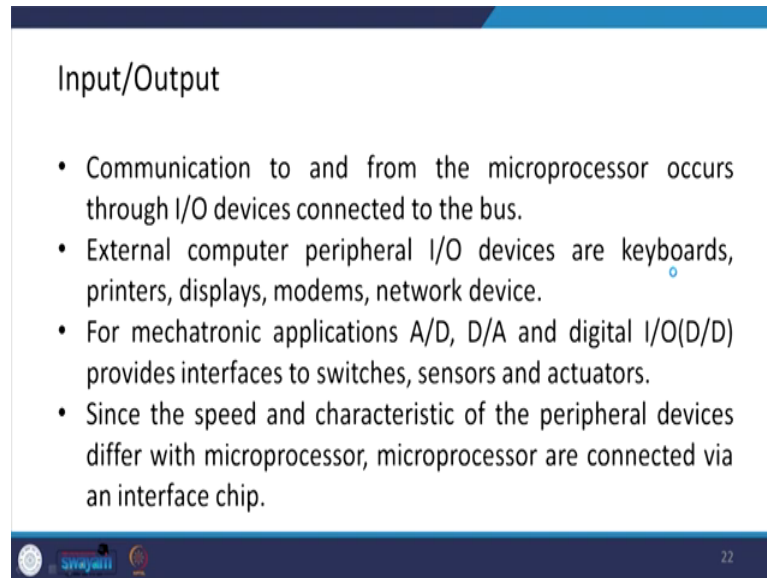

- Data stored can be erased with ultraviolet light through a transparent window at the top of the EPROM IC.
- Then new data can be stored on the EPROM.
- Other type of EPROM is electrically erasable (EEPROM)
- Data in this is electrically erasable and rewritten through its data line.

21

Next is the EPROM. This is an erasable programmable read-only memory, which is called EPROM. In this, the stored data can be erased with ultraviolet light through a transparent window at the top of the EPROM IC. The new data can be stored on the EPROM. Another

type of EPROM is electrically erasable; that is what we call EEPROM. And data in this is electrically erasable and rewritten through it is the data line.

(Refer Slide Time: 17:23)

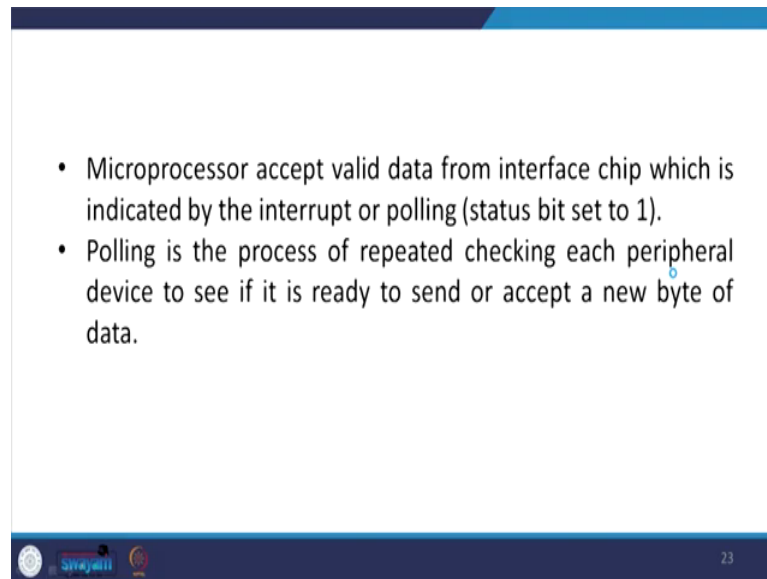

The slide is titled "Input/Output" and contains a bulleted list of four points. The first point states that communication to and from the microprocessor occurs through I/O devices connected to the bus. The second point lists external computer peripheral I/O devices: keyboards, printers, displays, modems, and network devices. The third point discusses mechatronic applications, mentioning A/D, D/A, and digital I/O(D/D) converters that provide interfaces to switches, sensors, and actuators. The fourth point notes that because the speed and characteristics of peripheral devices differ from those of the microprocessor, they are connected via an interface chip. The slide footer includes a logo on the left and the number "22" on the right.

Input/Output

- Communication to and from the microprocessor occurs through I/O devices connected to the bus.
- External computer peripheral I/O devices are keyboards, printers, displays, modems, network device.
- For mechatronic applications A/D, D/A and digital I/O(D/D) provides interfaces to switches, sensors and actuators.
- Since the speed and characteristic of the peripheral devices differ with microprocessor, microprocessor are connected via an interface chip.

Now, let us look at the input-output. So, the communication to and from the microprocessor occurs through the input-output devices connected to the bus. External computer peripherals input-output devices are keyboard, printer, displays, modems, network devices, and for mechatronic applications analog to digital converter, or digital to analog converter, and digital input-output. For example, digital to digital converter provides interfaces to switches, sensors, and actuators. Since the speed and characteristics of the peripheral devices differ with the microprocessor, microprocessors are connected via an interface chip.

(Refer Slide Time: 18:24)

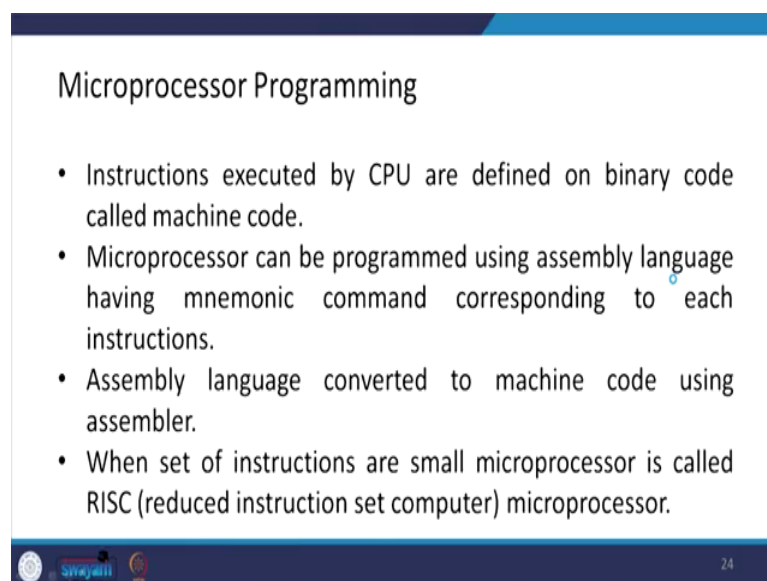

• Microprocessor accept valid data from interface chip which is indicated by the interrupt or polling (status bit set to 1).

• Polling is the process of repeated checking each peripheral device to see if it is ready to send or accept a new byte of data.

23

Microprocessor accepts valid data from interface chip which is indicated by the interrupt or polling the that is a status bit set to 1. Now, polling is the process of repeated checking each peripheral device to see if it is ready to send or accept a new byte of data.

(Refer Slide Time: 19:04)

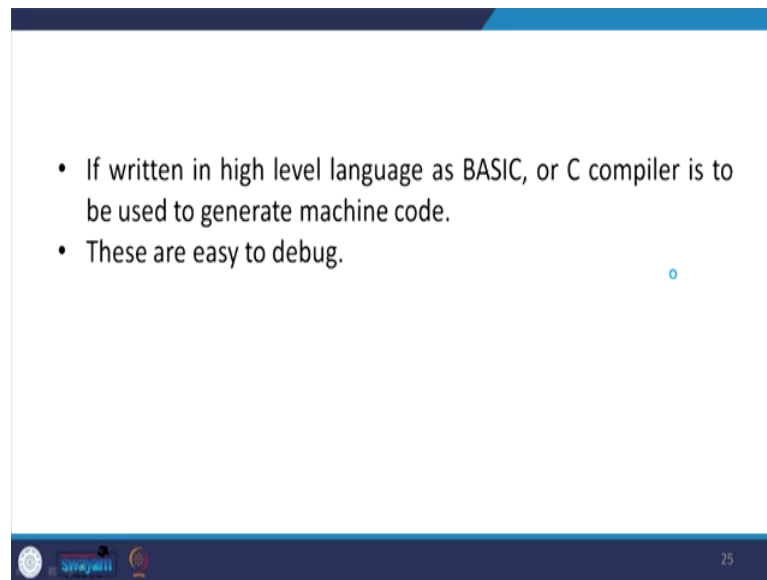

Microprocessor Programming

- Instructions executed by CPU are defined on binary code called machine code.
- Microprocessor can be programmed using assembly language having mnemonic command corresponding to each instructions.
- Assembly language converted to machine code using assembler.
- When set of instructions are small microprocessor is called RISC (reduced instruction set computer) microprocessor.

24

Now, let us look at the programming of the microprocessor. Instructions executed by the CPU are defined on binary code called machine code. Microprocessors can be programmed using assembly language having mnemonic commands corresponding to each instruction. Assembly language converted to machine code using the assembler. And when the set of instructions is small, the microprocessor is called RISC; that is the reduced instruction set computer microprocessor.

(Refer Slide Time: 19:37)

- If written in high level language as BASIC, or C compiler is to be used to generate machine code.
- These are easy to debug.

If written in a high-level language, as BASIC or C compiler is to be used to generate the machine code, and these are easy to debug.
