Module – 02
Lecture – 09
Wind Loads (Part – 1)

(Refer Slide Time: 00:16)

Friends welcome to the second module lectures, where this is lecture 9 in which we will discuss about wind loads. In the last lecture we discussed about wave spectra and one of the important source of offshore loads which is wave load. We also said what are the different varieties of loads acting on offshore structures, classification of loads where wave loads are predominantly important, let us talk about wind loads and see what spectra defines wind load and we will do some couple of examples then we will talk about the computer code to estimate wind loads.

(Refer Slide Time: 01:06)

Module 2
Lecture 9: Wind loads

- Wind loads - structures - complicated fluid-dynamics
 - In general, it is difficult to compute wind forces with higher accuracy.
- Most widely approach - few observations

- 1) when a stream of air flows with constant (velocity) speed (v), then it will generate force on a flat plate of area, A .
- 2) when the plate is placed orthogonal (\perp) to the flow direction

Wind loads actually add some structures which creates in fact, a very complicated fluid dynamics. In general it is very difficult to compute wind forces with higher accuracy, it is a general statement I will reinforce the statement slightly by **showing** you some theories of an examples, then the question comes what is the most widely used approach to estimate wind forces.

The widely used approach is based on few observations let us say what are they; one when a stream of air flows with constant velocity, let us the word speed because wind speed is important. Velocity v then it will generate force on a flat plate of area; interestingly this generates force on the plate when the plate is placed orthogonal that is perpendicular to the flow direction.

(Refer Slide Time: 02:36)

- This force will be proportional to Av^2

- The proportionality constant is independent of area (proved by many experimental studies)

Wind force, on the plate, placed orthogonal to the flow direction, is determined by estimating net wind pressure (p_w)

$$p_w = \frac{1}{2} \rho_a C_w v^2 \quad \text{--- (1)}$$

where ρ_a - mass density of air = 1.25 kg/m^3
 C_w - wind pressure coefficient

And this force which **exerts** on the plate will be proportional to $A v$ square. Now the proportionality constant is interestingly independent of area, this is proved by many experimental studies. References can be seen from the list of paper sited in the nptel course of this specific syllabus. Having said this we now say that the wind force exerted on a plate placed orthogonal to the flow direction is determined by estimating something called Net wind pressure, which say as p_w and w stands for wind small p stands for pressure.

So, small p_w is half $\rho_a C_w v$ square equation 1 where ρ_a is mass density of air taken as $1.25 \text{ kg per cubic meter}$ and C_w is wind pressure coefficient.

(Refer Slide Time: 04:40)

It is important to note that
mass density of air (ρ_a) increases due to water spray
in the splash zone
up to a height of 20-30m above
Mean sea level

ρ_a is not constant

Total wind-induced force, on the plate is given by:

$$F_w = \rho_w A \quad (2)$$

It is important to note that the mass density of air that is ρ_a increases due to water spray in this flat zone up to a height of about 20 to 30 meters above the mean sea level. So, it is important that ρ_a is actually not constant.

Now, the total wind induced force on a plate is given by capital F_w sp w into A interestingly.

(Refer Slide Time: 05:45)

wind flow coefft (C_w) - based on controlled stationary wind
flow conditions, experimentally

- wind tunnel
- depends on Reynolds Number (Re)

$C_w \approx 0.7$ to 1.2 for cylindrical members

If the plate is placed at an angle θ with respect to the flow direction, then one need to work out the projected area accordingly. For example, if this is my plate, which is normal

and this angle is theta and the plate has an area A, if this becomes my wind direction I need to work out the projected area ok.

So, one has to really carefully work out the projected area in the flow direction. Having said this the wind flow coefficient C_w is generally determined based on controlled stationary wind flow conditions experimentally, usually this is done in wind tunnel it depends on few factors the foremost important factor is Reynolds number of the flow usually C_w is taken as 0.7 to 1.2 for cylindrical members.

(Refer Slide Time: 07:38)

Natural wind - ② components

- 1) Mean wind component
(static component)
- 2) Fluctuating Gust component

Gust component is generated by turbulence in the flow field

- ③ spatial directions

In offshore location, mean wind speed $\gg \gg$ gust component

So, friends natural wind has actually got two components, one is the mean wind component which is a static component other is the fluctuating gust component. So, gust component actually is generated by turbulence, in the flow field. This happens in three spatial direction, but one good news is that in offshore locations it is been observed that the mean wind speed is much greater than the gust component. Having said this we can now say v of t is \bar{v} plus v of t .

(Refer Slide Time: 08:38)

$$V(t) = \bar{V} + v(t)$$
 mean gust component

\bar{V} - spatial dependence
 - is only through the vertical direction

$v(t)$ - homogeneous ← space time

Wind force

- F_D - Drag force - || to wind flow
 $= \frac{1}{2} \rho C_D V_z^2 A$
- F_L - Lift force - ⊥ to the wind flow
 $= \frac{1}{2} \rho C_L V_z^2 A$

C_D || Drag coefficient
 C_L || Lift coefficient
 A = Area, ⊥ to the wind flow direction

So, this is my mean component, this is my gust component now mean component as also have the spatial dependence, but it is assumed that the special dependence is only through the vertical coordinates. V of t is considered to be homogenous both in space and time. So, now, wind force in offshore structure can be calculated by 2 one is F D other is F L, F D is a drag force and F L is called the lift force which actually happens in the direction parallel to the wind flow.

This happens in the direction normal to the wind flow, this is given by half rho C D V z square A and this is given by half rho C L V z square A, where we already know C D and C L are drag and lift coefficients respectively and A is the area perpendicular to the wind flow direction.

(Refer Slide Time: 10:48)

Wind spectrum is used to calculate force above water surface

$$V_z = V_{10} \left(\frac{z}{10} \right)^{1/7} \quad \text{--- (3)}$$

$\frac{1}{7}$ power law

V_z - Wind speed @ elevation z m above the MSL
 10 - reference or datum height, 10 m above the MSL

V_{10} - wind speed @ 10 m above the MSL

Power law - empirical
- most widely used
- validated with actual measurements, found to be in good agreement

So, now wind spectrum is being used is used to calculate the force above water surface, which is given by V_z is equal to $V_{10} z$ by 10 to the power 1 by 7 this is also called as one seventh power law because the power is 1 by 7 .

V_z in this equation is the wind speed at elevation z meters above the mean sea level 10 refers to a reference or a datum height which is actually 10 meters above the mean sea level. So, friends it is very simple if you substitute z is equal to 10 here, you will see that up to 10 meter wind velocity remains constant of course, V_{10} is that wind speed at 10 meter above the mean sea level. So, there are some comments about the power law this is called as the power law power law is purely empirical, but most widely used and it is validated with actual measurements and found to be in good agreement. So, it is fairly a correct estimate.
