Basic Fiber Optics
Lecture - 14
Material Dispersion

Hello student. To the course of Physics of Linear and Non-Linear Optical Waveguides. Today, we have lecture number 14. And, in this lecture we are going to start the concept basic concept of Material Dispersion, which is very important in wave guide theory.

(Refer Slide Time: 00:31)

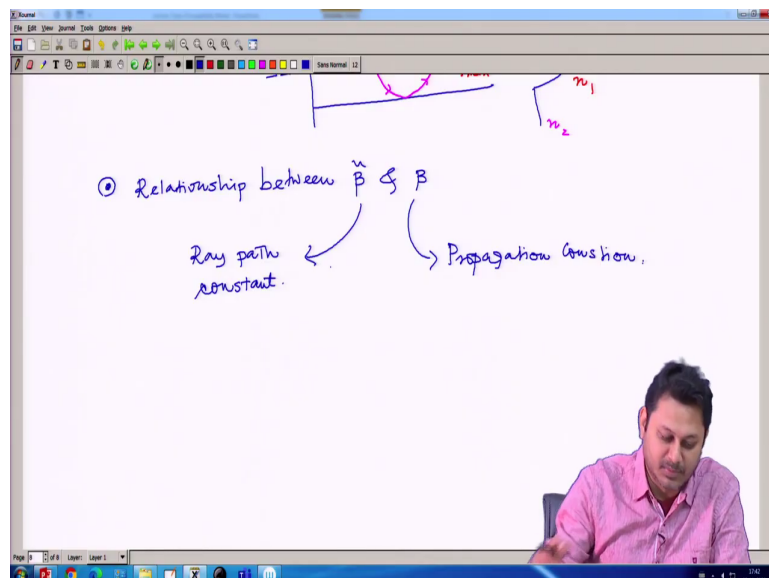

So, today we have lecture number 14. So, let us recap what we have done, that beta in the last class. That the beta tilde has some restriction, that it should be less than n_1 and greater than n_2

2 for all guided rays. For all guided rays inside a wave guide, these are the restriction of the beta. So, this is the fibre structure and this is the parabolic index profile. And, we find that the ray that is passing along the axis have the value of β maximum, which is equal to n_1 .

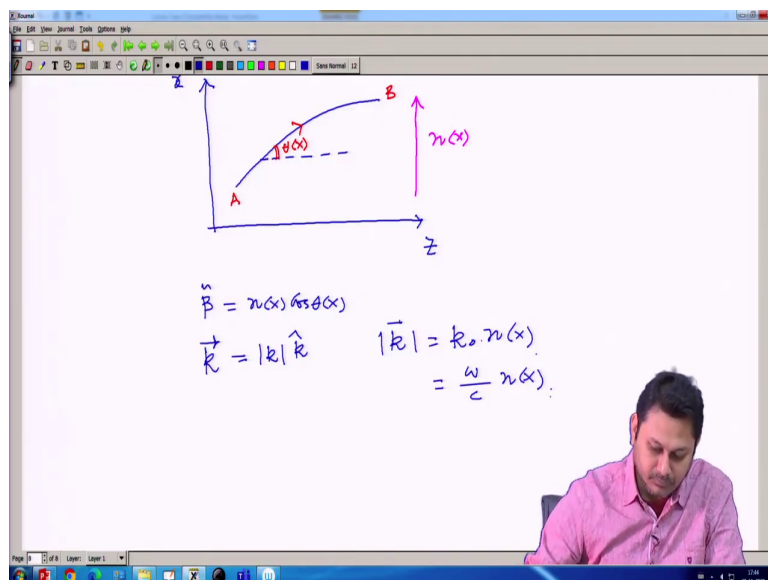

And, the ray that is moving like this, touching this point, the transit point, having an angle θ_0 for that β is minimum and that value is equal to n_2 . Where n_2 is this 1, n_2 is this 1, and n_1 is this peak value.

(Refer Slide Time: 02:53)

So, today we will going to understand another thing before going to the material dispersion part. That the relationship between relationship between β and $\tilde{\beta}$. What is the relationship between β and $\tilde{\beta}$? This is by the way is ray path constant and this is propagation constant. Where, $\tilde{\beta}$ do not have any kind of dimension, the propagation constant β has dimension 1 by length, that you should always remember.

(Refer Slide Time: 04:06)

Well, let me again draw this two dimensional plane, where the ray is passing like this. So, when the ray is passing like this. In this path from point some point A to B every point this theta is changing. So, at some point say it is theta x and as usual along this direction we have the refractive index change of refractive index in x. So, beta tilde is n x cos of theta x true always.

Now, what is k the propagation constant? k is in general is a vector quantity, it is mod of k and k unit vector is the direction along which the ray is propagating the k is direction of that part, that direction. And, mod of k is k 0 multiplied by the refractive index, because refractive index is changing every time. So, n should be a function of x. So, that is the so, this value is omega divided by c n x. What is k z? So, the z component of so; that means, if the ray is passing like, if the ray is passing in this path.

(Refer Slide Time: 06:17)

$$k_z = |k| \cos(\theta) = \beta$$

$$\beta = k_0 n(x) \cos(\theta) = k_0 \tilde{\beta}$$

$$\tilde{\beta} = \frac{\beta}{k_0}$$

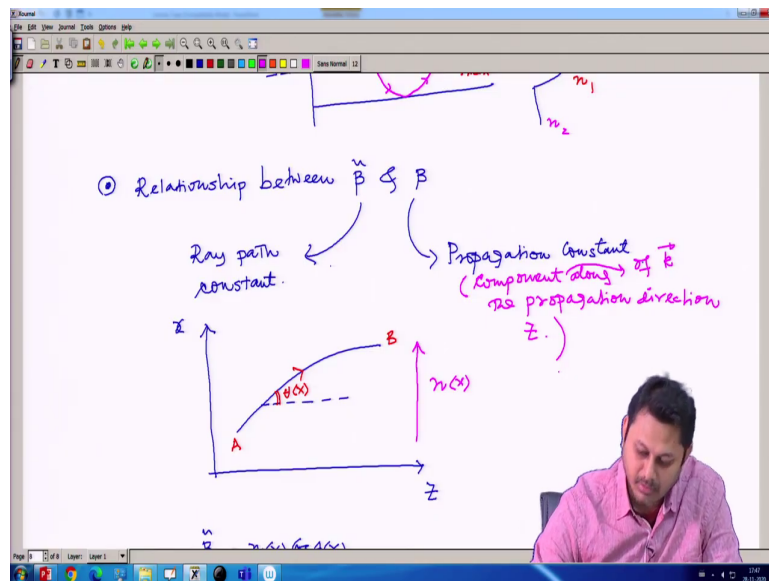

$$n_2 < \tilde{\beta} < n_1 \longrightarrow n_2 < \frac{\beta}{k_0} < n_1$$

(For all the guided rays)

So, this is the k vector we have. If I want to find out the component of the k vector along this direction this is along z . So, this is k_z component. And, what is k_z component? It is nothing, but $\text{mod of } k$, then \cos of θ function of x , which is by the way my β .

So, β is a propagation constant along the direction of z and k is the propagation constant, so, β is the specific. So, it is the z component of the propagation constant. So, β here so, propagation constant is a there is a component of the propagation constant, the component along, the propagation direction z so, I.

(Refer Slide Time: 07:18)

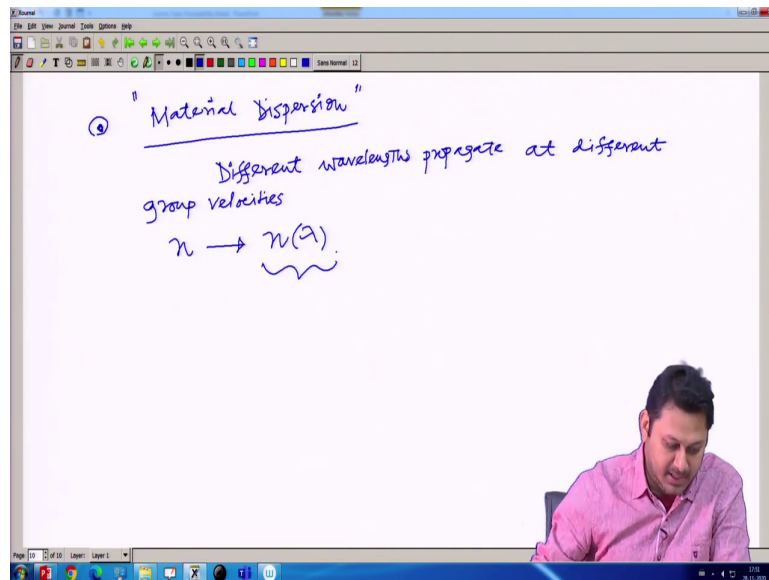

So, now I just put this value so, my beta which is a z component of the propagation vector k is 2. So, here I should write the component. So, I should write clearly component of propagation vector. So, component so, here I should write it component of what so, component of k along the propagation direction z .

So, beta is k_0 so, let me erase this part. So, my beta is how much? $k_0 n(x) \cos \theta$, that is all. Now, this $n(x) \cos \theta$ is my beta tilde. So, it is eventually k_0 multiplied by beta tilde. So, beta tilde is nothing but beta divided by k_0 . So, the restriction we had last time is beta tilde for guided mode, beta tilde is less than n_1 greater than n_2 can be rewritten in terms of beta as a propagation constant like, n_2 is less than beta divided by k_0 is greater than n_1 .

So, this is a very important restriction of all the guided for; all the guided for all the guided rays. This important restriction, that we will going to explore more in our future classes ok.

(Refer Slide Time: 10:55)

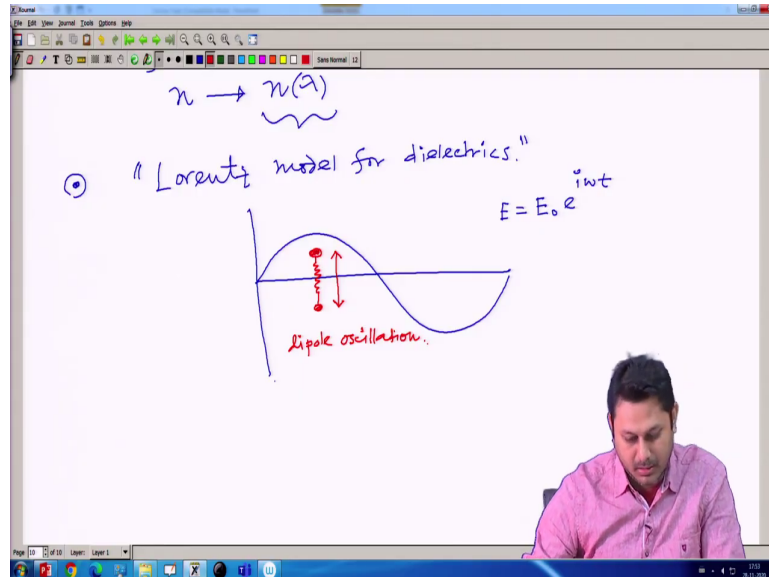

After, that we will directly jump to one of the major property of waveguide, which is called the material dispersion, material dispersion. So, quickly we brush up the material concept of material dispersion. So, different wavelength is nothing but the different wavelength propagates at different group velocities. So, different wavelength propagate at different so, that happens because n is a function of λ . So, that is the main issue here. So, the refractive index n is a function of λ .

So, that is the reason due to which the wave having λ_1 and the wave is having λ_2 , has 2 different group velocities. So, that we are going to explore in a more detailed manner.

But, before that we need to find out how n is a function of λ ? What is the functional form?

(Refer Slide Time: 13:11)

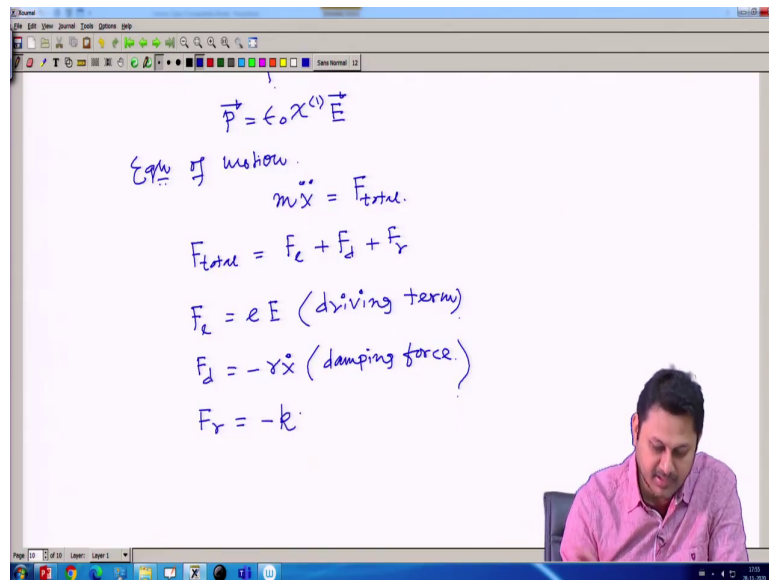

And, in order to do that we going to use are going to refresh the “Lorentz model for dielectrics”. So, Lorentz model for the dielectrics we try to understand, this is not a very new thing, but still I feel that, it will be useful for you to understand the concept of dispersion. In a dielectric if I launch an electric varying electric field like this, there is the varying electric field, electric field, I can write as $E_0 e^{i\omega t}$.

So, some frequency ω the electric field is launched having some frequency ω . So, what happened the dielectrics this dipole will going to oscillate, under the varying oscillating external electric field. So, there should be a dipole oscillation. Now, we know what is the

polarization? Because, the refractive index is the consequence of the polarization of the system, especially for dielectric system.

(Refer Slide Time: 15:03)

$$\vec{P} = \epsilon_0 \chi^{(1)} \vec{E}$$

Eqn of motion:

$$m \ddot{x} = F_{\text{total}}$$

$$F_{\text{total}} = F_e + F_d + F_r$$

$$F_e = e E \text{ (driving term)}$$

$$F_d = -\gamma \dot{x} \text{ (damping force)}$$

$$F_r = -k x$$

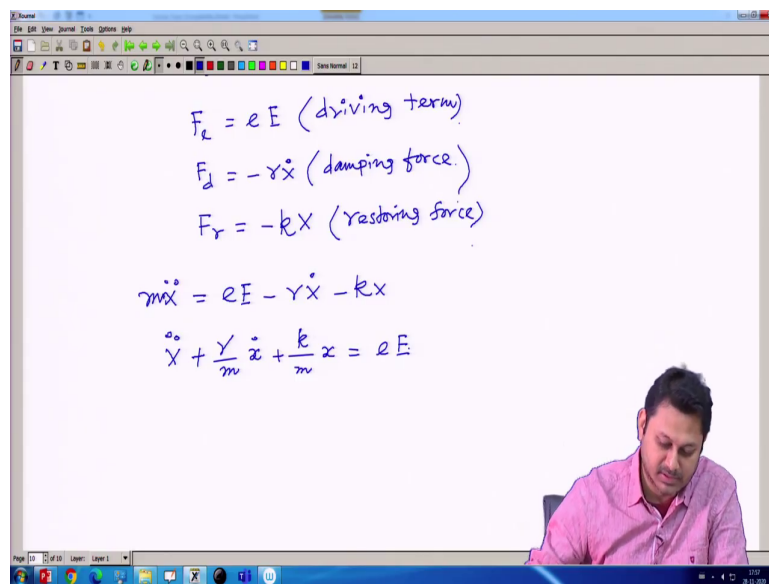

So, polarization P in vectorial form if I write it is this quantity. If I consider only the linear part of that linear polarization, then this is the expression. Obviously for non-linear cases there will be higher order term.

So, we are not going to the non-linear domain right now. For linear case P is simply $\epsilon_0 \chi^{(1)} E$. Now, the equation of motion, if I want to find out what is the equation of motion of this system? So, the equation of motion is $m \ddot{x}$ is equal to the total force.

Now, what is the total force? So, the total force experienced by this tiny dipole is like that, F_{total} is a combination of the 3 term F_e , F_d and F_r . What is F_e ? F_e is the driving term due

to the external electric field. What is F_d ? F_d is minus of $\gamma \dot{x}$ this is velocity dependent term and this is basically the damping term so, damping force actually. So, the F_e is a driving force or driving term, F_d is a damping force and F_r , which is minus of kx because we are considering that is this spring mass like a spring mass system dipole is oscillating, it is kx is a restoring force.

(Refer Slide Time: 17:29)

$$F_e = eE \text{ (driving term)}$$

$$F_d = -\gamma \dot{x} \text{ (damping force)}$$

$$F_r = -kx \text{ (restoring force)}$$

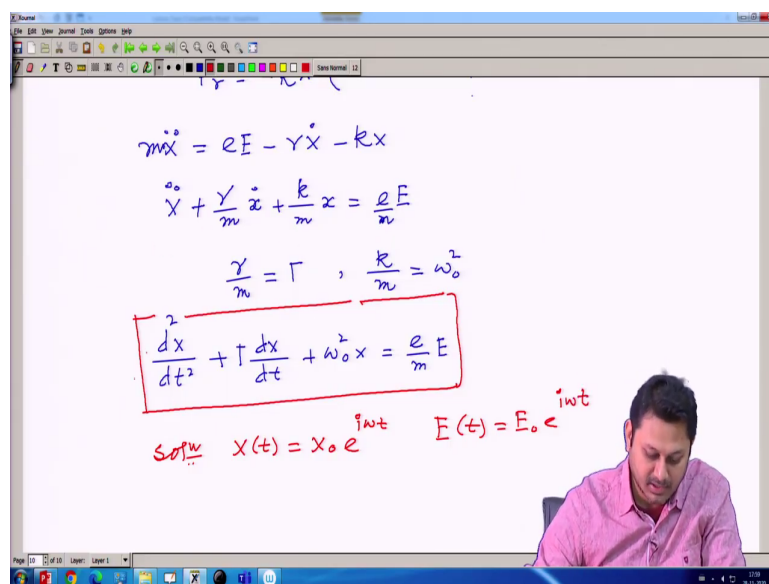

$$m\ddot{x} = eE - \gamma \dot{x} - kx$$

$$\ddot{x} + \frac{\gamma}{m} \dot{x} + \frac{k}{m} x = \frac{eE}{m}$$

This all these things are well known so, I do not need to explain much, I just need to extract the expression of the refractive index out of this model. And, then it will be readily evident that how the refractive index is a function of λ ? That is all that is the goal of this treatment. So, I just put the values like this and then x double dot is equal to $\frac{eE}{m}$. So, let me write few step, then I will going to calculate that.

So, x double dot plus γ divided by m x dot plus k divided by m x is equal to the driving term $e E$. Mind it k here is a spring constant not the propagation constant, this is different things. So maybe the notation looks same, but the k is the spring constant usual, coming usually from the Hooke's law.

(Refer Slide Time: 19:01)

$$m\ddot{x} = eE - \gamma\dot{x} - kx$$

$$\ddot{x} + \frac{\gamma}{m}\dot{x} + \frac{k}{m}x = \frac{eE}{m}$$

$$\frac{\gamma}{m} = \Gamma, \quad \frac{k}{m} = \omega_0^2$$

$$\boxed{\frac{d^2x}{dt^2} + \Gamma \frac{dx}{dt} + \omega_0^2 x = \frac{e}{m} E}$$

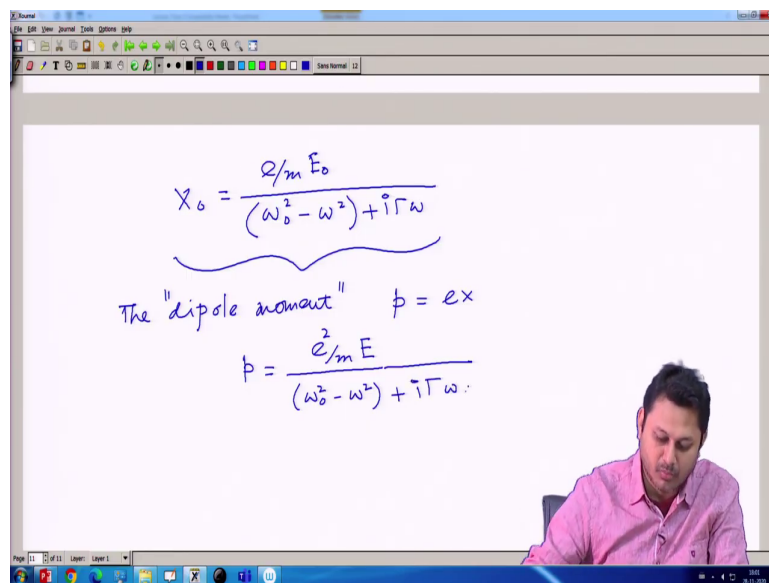

soln $X(t) = X_0 e^{i\omega t}$ $E(t) = E_0 e^{i\omega t}$

Now, I defined a γ divided by m is a damping term as big γ and k divided by m with our usual ω square, which is a resonance frequency of the system, that we know. That in a spring mass system, the resonance frequency is nothing but root over of k/m that I am just using this that one. So, my differential equation becomes simply d^2x/dt^2 plus γ dx/dt plus $\omega_0^2 x$ is $e/m E$, when I divide it should be $e/m E$.

So, this is the differential equation now I need to solve. So, this differential equation is nothing but the force damped oscillation expression a very well known x differential equation nothing special here. And, we know how to solve this. So, the solution I want in this form. So, solution I should have in this particular form, e to the power i of ωt . Because, the electric field against the electric field, which is e external electric field the x will also follow the same vibration frequency. And, I am expecting the solution in this form.

Once, I have this solution and this assume that the solution in this form, I can readily calculate my x_0 just putting this solution here in this equation, putting this solution in this equation. I can readily find out my x_0 as e divided by $m E$ as usual divided by now, I put this value here.

(Refer Slide Time: 21:20)

$$x_0 = \frac{e/m E_0}{(\omega_0^2 - \omega^2) + i\Gamma\omega}$$

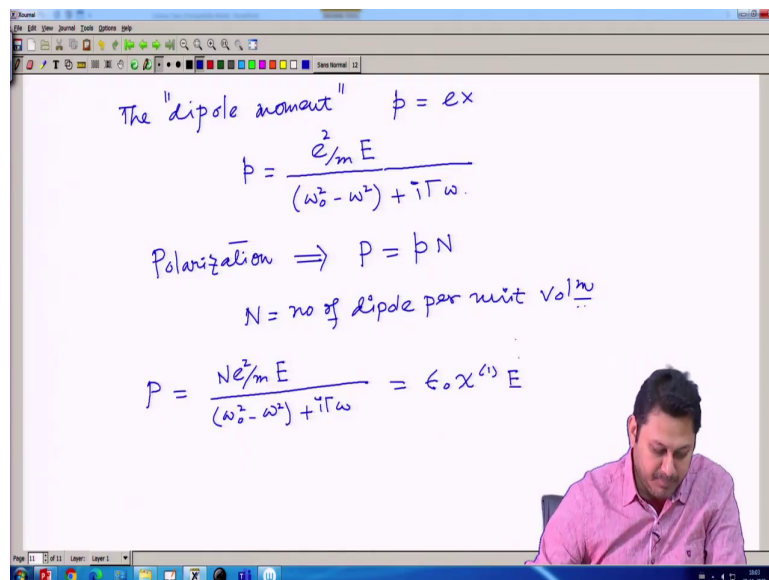

The "dipole moment" $p = ex$

$$p = \frac{e^2/m E}{(\omega_0^2 - \omega^2) + i\Gamma\omega}$$

So, double derivative when I make a double derivative there should be a minus of omega square. So, an omega square is already here. So, it should be simply omega square minus, omega square plus i gamma omega and it should be E 0, because I am calculating x. So, from this expression, I can calculate the “dipole moment”. The dipole moment is simply p the dipole moment is simply charge multiplied by the distance x.

So, here it should be p equal to e square divided by m, then e whole divided by that quantity omega square minus, omega square omega 0 square minus, omega square I gamma omega.

(Refer Slide Time: 22:58)

The "dipole moment" $p = ex$

$$p = \frac{e^2/m E}{(\omega_0^2 - \omega^2) + i\Gamma\omega}$$

Polarization $\Rightarrow P = pN$

$N = \text{no of dipole per unit vol}^{\text{m}}$

$$P = \frac{Ne^2/m E}{(\omega_0^2 - \omega^2) + i\Gamma\omega} = \epsilon_0 \chi^{(1)} E$$

Polarization, if I want to calculate, because I started with the expression of the polarization. Because, the refractive index the information is of refractive index is hidden here. So, I need to extract that this portion, I need to extract that. So, the polarization is P, which I can write

dipole moment. And, n is a number of dipole per unit volume. So, dipole moment per unit volume is my polarization. So, n here is the number of dipole per unit volume.

So, I can write my P in terms of small p n and my small p already I calculate. So, it is the expression is simply $N e^2$ divided by m , then E divided by $\omega_0^2 - \omega^2 + i \gamma \omega$, which is basically $\epsilon_0 \chi^{(1)} E$.

(Refer Slide Time: 24:52)

The slide contains the following handwritten equations:

$$P = \frac{Ne^2/m E}{(\omega_0^2 - \omega^2) + i\gamma\omega} = \epsilon_0 \chi^{(1)} E$$

$$\chi^{(1)} = \frac{e^2 N/m \epsilon_0}{(\omega_0^2 - \omega^2) + i\gamma\omega}$$

$$\begin{aligned} \epsilon_r(\omega) &= 1 + \chi^{(1)}(\omega) = \epsilon_r(\omega) \\ &= 1 + \frac{e^2 N/m \epsilon_0}{(\omega_0^2 - \omega^2) + i\gamma\omega} \\ &= 1 + \frac{\omega_p^2}{(\omega_0^2 - \omega^2) + i\gamma\omega} \end{aligned}$$

Where $\omega_p = \frac{eN}{m}$ is written in red on the right side of the slide.

So, now, comparing this to expression I can extract the value of $\chi^{(1)}$. My $\chi^{(1)}$ susceptibility first order susceptibility is $e^2 N$ divided by $m \epsilon_0$. I just divide this ϵ_0 and then compare that, whole divided by whatever the term I already have $\omega_0^2 - \omega^2 + i \gamma \omega$. Now, my ϵ_r which readily become function of ω , because it is related to $\chi^{(1)}$ as $1 + \chi^{(1)}$. $\chi^{(1)}$ I can find this is a function of ω .

So, through chi 1 I can have the value of n square, which becomes a function of omega. So, I can again this quantity is nothing but the relative susceptibility, relative permittivity. So, now, I have 1 plus e N divided by m epsilon, whole divided by omega 0 minus, omega square plus, i gamma omega. This quantity normally written in a more compact form so, let me write it compact form in terms of plasma frequency. So, this is like this is a constant ok. I think, I am missing 1 e square here.

(Refer Slide Time: 27:22)

The image shows a handwritten derivation on a whiteboard. The equations are as follows:

$$\chi_1(\omega) = 1 + \frac{\omega_p^2}{(\omega_0^2 - \omega^2) + i\Gamma\omega}$$

where the plasma frequency is defined as:

$$\omega_p = \frac{eN}{m\epsilon_0}$$

labeled "Plasma Frequency".

$$\chi_1(\omega) = 1 + \frac{\omega_p^2[(\omega_0^2 - \omega^2) - i\Gamma\omega]}{[(\omega_0^2 - \omega^2)^2 + \Gamma^2\omega^2]}$$

$$= 1 + \frac{\omega_p^2(\omega_0^2 - \omega^2)}{(\omega_0^2 - \omega^2)^2 + \Gamma^2\omega^2} - \frac{i\omega_p^2\Gamma\omega}{(\omega_0^2 - \omega^2)^2 + \Gamma^2\omega^2}$$

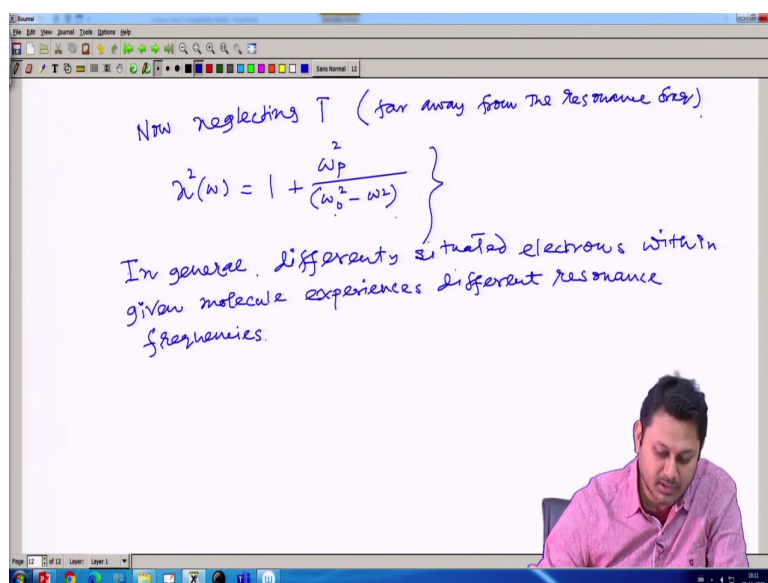

The imaginary part is indicated as "Loss" with a downward arrow.

So, this is e square and then m epsilon 0. This is a plasma frequency term. Well, N of omega, I can now find one interesting thing, that n square omega is complex. And, if I just remove try to write it as standard form a plus i v x plus i y form or a plus i b from. So, here I think, I should have a negative sign. And, the denominator I have multiply the numerator and denominator by omega 0 square minus omega square minus i gamma omega.

Then, this will have term like $1 + \omega_p^2 / (\omega_0^2 - \omega^2)$, this is the real part I am extracting out. And, the denominator it should be simply $\omega_0^2 - \omega^2 + \gamma^2$, here I should have a square minus ω^2 , whole square, then plus of γ^2 , ω^2 . And, then minus of $i \omega_p \gamma / (\omega_0^2 - \omega^2 + \gamma^2)$. So, this is a part containing the complex term.

And, this term is basically due to gives us a loss. The refractive index, if I have a complex term it gives us a loss. So, the refractive index contribution is coming through the first term, that is interesting and that I need to just mention. So, now, this γ is loss. If I neglect the loss and I can neglect that when the frequency is far away from the resonance frequency of the systems.

(Refer Slide Time: 30:25)

Now neglecting γ (far away from the resonance freq.)

$$\chi^2(\omega) = 1 + \frac{\omega_p^2}{(\omega_0^2 - \omega^2)}$$

In general, differently situated electrons within given molecule experiences different resonance frequencies.

So, in that case now neglecting sorry gamma, so, which is far away from the resonance frequency then, I can write n^2 as $1 + \frac{\omega_p^2}{\omega_0^2 - \omega^2}$ ok. So, this is roughly the expression and from here we can readily see that how the refractive index is a function of omega? But, that is not the end.

In general what happened, differently situated electrons within a given molecule, experiences different resonance, resonance frequencies. Because, all the in this calculation, we consider the resonance frequency for all the electrons is same, which is not true.

(Refer Slide Time: 32:54)

Handwritten on the whiteboard:

$$n^2(\omega) = 1 + \frac{\omega_p^2}{(\omega_0^2 - \omega^2)} \left\{ \right.$$

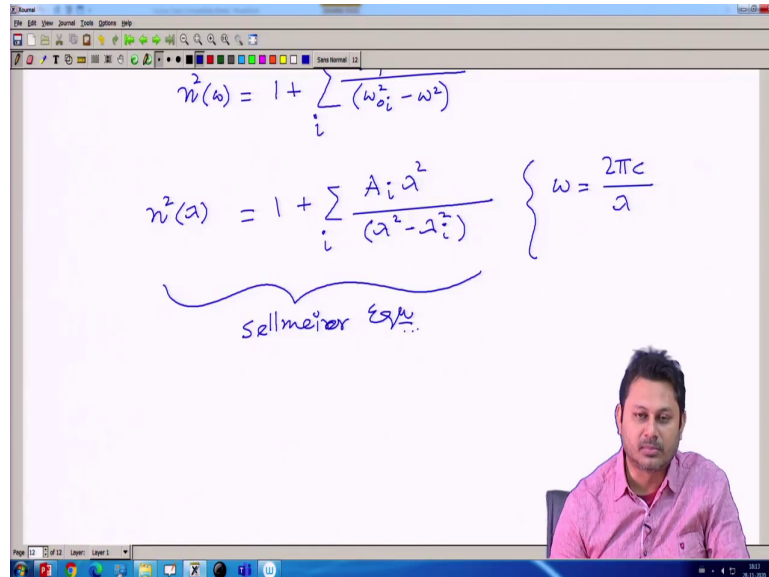

In general, differently situated electrons within given molecule experiences different resonance frequencies.

$$n^2(\omega) = 1 + \sum_i \frac{\omega_{pi}^2}{(\omega_{0i}^2 - \omega^2)}$$

So, I need to consider that as well. So, n omega should be written in this particular form. For every the resonance frequency is now different for different differently situated electrons. So,

I need to take account that as well by putting the summation sign. So, for different I have different resonance frequency.

(Refer Slide Time: 31:31)

$$n^2(\omega) = 1 + \sum_i \frac{A_i}{(\omega_{0i}^2 - \omega^2)}$$

$$n^2(\lambda) = 1 + \sum_i \frac{A_i \lambda^2}{(\lambda^2 - \lambda_{0i}^2)} \quad \left\{ \begin{array}{l} \omega = \frac{2\pi c}{\lambda} \end{array} \right.$$

Sellmeier eqn.

And, then I can have an expression, if I now write this expression in terms of lambda, I have something like this. Some constant say, $A_i \lambda^2$ divided by $\lambda^2 - \lambda_{0i}^2$ using, the expression of the relationship between omega and lambda. This equation is basically called the Sellmeier equation. So, Sellmeier equation is the equation through which you can understand how the refractive index will going to vary with respect to lambda.

So, with this note I like to conclude, because today we do not have much time. In the next class, we will go on with this concept. So, now, from today's class we understand that a refractive index is a function of lambda. And, that is why when we launch a light with

different frequency component, it will pass through the system with the different velocity group velocity, because n is changing as a function of λ . And, that is why there is a time lag between these two component frequency component of the wave and eventually we have the dispersion.

So, we will discuss these things and also like to learn how because of the dispersion there is a broadening of a optical pulse. So, let us do in the next class all this calculation.

So, thank you for your attention and see you in the next class.
