Lecture - 43: Fresnel Diffraction

Hello, student; welcome to the wave optics course. Today, we have lecture number 43, and today, we are going to start a new topic, which is called the Fresnel diffraction. So today, we have lecture number 43. I'm going to start today with a new topic, as I mentioned, which is Fresnel's diffraction. So before that, let me quickly remind you that the phenomena of diffraction were broadly divided into two types: Fraunhofer diffraction and Fresnel diffraction. So, in Fraunhofer-type diffraction, you may remember that the source and the screen are both at infinity because the structure is something like this. So essentially, we deal with this as the source, where the light is emitting, and then we place a lens here. We can have a parallel ray that makes the incident like the source infinity, then we have some aperture here, and then again we place a lens here and on the screen. So suppose light is diffracted, and then we accumulate all the light here at some point P, and we find a pattern here, but essentially, the source and screen are both at infinity. This is the source, and that is the screen. Fresnel diffraction, on the other hand, is the structure; it is simple. If I have a source here, it emits light and interacts with this aperture, and then we will get some pattern here out of that. In this case, what happens is that light that falls to the aperture will be a spherical wave, and then that coming here and reaching here is also a spherical wave since both are infinite. The setup is simple, and we will get a pattern here. On the other hand, in Fraunhofer's case, the light that is coming here, that is heading to this aperture, is not a spherical wave; rather, this is a plane wave, and whatever I get is captured here in this screen. This case is the source, and it is screened. Different cases are discussed under Fraunhofer's diffraction problem. For example, we discussed the single-slit problem. We discussed the double slit problem. We exchanged this idea to discuss the multi-slit problem, and then we discussed also what happened for circular aperture and rectangular aperture. So, we discussed these five problems in detail with all the calculations for Fraunhofer diffraction cases. Now, we are going to do something similar in Fresnel's diffraction cases, but you will see that the treatment will be completely different here. The basic reason behind that is the light that is coming here is no longer considered to be a plane wave; rather, it will be considered to be a spherical wavefront that is coming, and based on that, we are going to do all the treatment. So, before solving the problem here in the Fresnel diffraction case, we will try to develop the theory and the background mechanism to get an intensity at point P. So, let us start with that. So, in Fresnel's case, what we do is this. So, we will start today with a basic understanding of Fresnel's diffraction. So, as I mentioned here, the source and the screen are in the finite distance, they're in the finite distance. So let me draw here that if this is a source and what happened from this source spherical wavefront I'm going to emerge and let me draw a portion of this spherical wavefront, it will emerge like this I am just drawing a portion of this wavefront which is no longer plane but spherical in nature and then we have an aperture here through which the light will fall. So, let me draw that first. So this is the window, and here we

have a window like this is O, so this is a point, say, this is a small cross-sectional area, and the light that is coming to this point is, say, R prime, and this is my S and the light that is coming through this window is some point here that is P and this is R. This cross-section is DA, the cross-sectional area. This is the point O, and this is the structure we have in our hand. Okay, so the electric field at point o in the aperture at this point here the electric field. So let me write about this point. So this o, that is the origin, and this is another point say o prime. So the electric field, O prime that is the area having the small area D that patches in the aperture is E_{naught} is equal to E_s divided by r prime e to the power of $i k r$ prime minus ω t . So note that this is a spherical wavefront that's why the 1 by r prime term is there, which was not before in the case of Fraunhofer diffraction problems. Now this quantity e is divided by r prime e to the power $i k r$ prime is considered to be a complex amplitude that we know that E , I can write it as $\text{minus } \omega$ t and this E_0 tilde is basically the complex amplitude. This is a complex amplitude. Now, the contribution to the resultant field at point P is due to all small areas. So, due to this small area, what is the contribution if I try to find out that contribution here, I can write that is, the contribution to the resultant field at P due to the small area dA that should be dE_p is equal to $d e$ naught divided by r e to the power of $i k r$ minus ω t , since p is in the finite distance. So the wave that is coming from this d area will also be a spherical wave. And if it is a spherical wave, then that should be the form 1 by r e to the power $i k r$ minus ω t , which is the form of the spherical wave. And $d e$ naught is a small amount of magnitude that is there. So, note the amplitude here. So, the amplitude, which is $d e$ naught divided by r , which is the amplitude that is proportional to the area dA . That is, if dA is large, then the contribution of the electric field will be large at the point P. So, I can write it as dE_0 by R is essentially, I just write E_a by R dA in this way, where E_a is the field amplitude per unit area. If dA is a field amplitude per unit area, then dA multiplied by area is a field amplitude. So, this is a field amplitude divided by R . On the left-hand side also, I have an amplitude divided by R . So, dimensionally, it is fine. So, now, E_a , is again proportional to the complex amplitude of the original electric field that is falling here.

(Refer slide time: 16:15)

• Fresnel Diffraction.

• The source & the screen are in finite distance.

The electric field at O' in the aperture.

$$E_0 = \frac{E_s}{r'} \cdot e^{i(kr' - \omega t)} = E_0 e^{i(kr' - \omega t)}$$

$\frac{E_s}{r'} e^{i(kr')} = \text{complex amplitude.}$

Contribution to the resultant field at P due to the small area dA

$$dE_p = \frac{dE_0}{r} e^{i(kr - \omega t)}$$

And $d e$ naught is a small amount of magnitude that is there.

So, if I go back and see that dE_0 is somehow related to the amount of field that is coming

from S, we can have that E_a should be proportional to A , and if that is the case, I can write that E_a is proportional to the complex amplitude, that we had earlier and that is $e^{i(kr - \omega t)}$ and what was $e^{i(kr - \omega t)}$ where let me write down $e^{i(kr - \omega t)}$ was E_s divided by r prime $e^{i(kr - \omega t)}$ to the power of $i(kr - \omega t)$ that we already had. So E_a is essentially a constant α , this is proportional science, and this is a constant α that will be multiplied by this it's a proportionality constant here, so E_s by r prime, $e^{i(kr - \omega t)}$ to the power of $i(kr - \omega t)$ that we have. So if E is known then from this expression that dE_p is E_0 by R . So, that I can write. Okay So, let me see what notation we use here. Here we use the small area y E_0 by A , I write E_a , and E_a is this quantity. So, essentially, we can have this. So, dE_p , which is equal to E_0 divided by R is $E_a r dA$, and E_a is this, so I can write α directly, then E_s divided by $r r'$. Then I have E to the power of $i(kr - \omega t)$. multiplied by $e^{i(kr - \omega t)}$ to the power of $i(kr - \omega t)$, I just put the value and that value if I simplify because one is $e^{i(kr - \omega t)}$ and another is $e^{i(kr - \omega t)}$ to the power $i(kr - \omega t)$. So I can write it as $\alpha E_s r r' e^{i(kr - \omega t)}$, then I have $k r$ plus, r prime minus ωt and then I should have a dA here. So I correlate the source, and then I have an aperture here with a small area and a point here p , and the light is going like this So, I correlate the electric field here to whatever I have here, which is E_p , and it is related to this area dA . So, now I want to find out what should be the total field here, then, what we are supposed to do is we just need to integrate over this aperture, and that we do. So, the total field at P is E_p and essentially, that should be the integration over dm . So it is equal to αE_s , then we have $e^{i(kr - \omega t)}$ term, which should come outside because that has nothing to do with the integral over an area, then we integrate over the entire aperture, and we have 1 divided by $r r' e^{i(kr - \omega t)}$ over dA . So that is the total expression we have and that expression suggests how the total field at P is related to the field at S . And if I know everything, then by doing this integration, I can find out the field that is there at P . So that is the structure. But in this calculation, a few things are neglected. Let me, in the book, you will find these factors. And that thing we are going to neglect here.

(Refer slide time: 25:33)

(Amplitude) $\frac{dE_0}{r} \propto dA$

$$\frac{dE_0}{r} = \frac{E_A}{r} dA$$

$E_A \rightarrow$ Field amplitude per unit area.

$$E_A \propto \vec{E}_0$$

$$\vec{E}_0 = \frac{E_s}{r} e^{i(kr - \omega t)}$$

$$E_A = \alpha \left[\frac{E_s}{r} e^{i(kr - \omega t)} \right]$$

$$dE_p = \alpha \frac{E_s}{r r'} e^{i(kr - \omega t)} \times e^{i(kr - \omega t)} dA$$

$$= \alpha \frac{E_s}{r r'} e^{i[k(r+r') - \omega t]} dA$$

The total field at $P \Rightarrow E_p = \alpha E_s e^{-i\omega t} \int \frac{1}{r r'} e^{i(k(r+r'))} dA$

Aperture.

But in this calculation, few things are neglected.

So, E_p , let me write down once again that E_p is equal to αE_s , then $e^{i(kr - \omega t)}$ to the power of

minus $i\omega t$, and then over the aperture we have 1 divided by $r r'$ to the power of $ik r + r' dm$, that is the overall integral. But a few things as I mentioned are neglected. The first thing is this expression does not take account of the obliquity factor, normally this obliquity factor we written as $F(\theta)$, and expression-wise $F(\theta)$ is half of one plus $\cos(\theta)$. So what is the obliquity factor? If I have a source here, if I want to find out something here then θ is zero. From this, I can get the $F(\theta)$ value, which is 1 . But if I move to another point here, this is my P and if I move to another point P_1 then I am with this horizontal line, I am making an angle θ , and as soon as I am making angle θ the factor. So, we are going to reduce the amplitude we are going to reduce here because of this obliquity factor, and if I move more and more wide angles then this value will change. So, that value is essentially called the obliquity factor and we neglect it here in this calculation. We consider that if you go back to the figure we consider that for whatever the ray I draw has nothing to do with the angle θ but which is not essentially the case. But we neglect it here for simplicity. Also, another thing is neglected here in this expression, when we calculate the total field by taking into account the integral over this aperture does not take. So, $\pi/2$, there is a $\pi/2$ phase shift of the diffracted wave related to the primary diffracted waves relative to the primary incident wave, and that $\pi/2$ factor is not. We didn't take this into account. So, we will discuss this in the coming few classes about how these things are there. So, let me first turn. So, do not take it into account. Let us now take into account the $\pi/2$ phase shift of the refracted wave relative to the primary incident wave we're going to discuss this in the coming few classes. So that condition is also not taken into account in this treatment so, that is the overall thing. So today I don't have much time to go forward with this idea but the point is today I try to develop from a very straightforward expression, which is a spherical wave that is emerging from a source and if it is hitting some aperture then it get diffracted by this aperture and we are going to get some some pattern at the screen. So if this pattern emerges then what should be the electric field that we calculate with this expression, that is shown here. So in the future classes, we will be going to exploit this expression and try to find out what the total field is by doing certain integration etcetera. But there are other simple methods that we need to learn before and in the next class we are going to do exactly the same thing and we will learn something called Fresnel's zone construction, that how by not doing that rigorous calculation. By simply using the concept of zone, we try to find out the intensity or at least get the idea of the intensity at some point due to some aperture. Okay, so with that note, I would like to conclude here in today's class. Thank you very much for your attention and see you in the next class.

(Refer slide time: 32:04)

$$E_p = \alpha E_s e^{-i\omega t} \int_{\text{Aperture}} \frac{1}{r r'} e^{ik(r+r')} dA.$$

1. Does not take account the obliquity factor. $F(\theta)$
 $F(\theta) = \frac{1}{2} (1 + \cos \theta)$

2. Does not take into account the $\frac{\pi}{2}$ phase shift of the diffracted waves relative to the primary incident wave.

diffracted by this aperture and we are going to get some some pattern at the screen
