Lecture - 40
Quantum Liquids and Quantum Solids – Worked Examples

(Refer Slide Time: 00:21)

Worked Example 104

Problem

Show that the chemical potential μ of a Bose gas is always less than or equal to zero.

Today, we will work out some examples on the topic of quantum liquids and quantum solids. The first example is one in which we are asked to show that the chemical potential typical symbol is mu of a Bose gas is always less than or equal to zero.

(Refer Slide Time: 01:02)

Solution

For a Bose gas we have the distribution function:

$$n(E_i) = \sum_i \frac{g_i}{\left\{ \exp \frac{(E_i - \mu)}{k_B T} \right\} - 1}$$

If $\mu > 0$ then for some $E_i < \mu$, the denominator will become negative but a negative occupation probability has no meaning. Therefore $\mu \leq 0$

We know that for a Bose gas the distribution function has the typical form, that is the typical form of the distribution function. Suppose μ is greater than zero then what happens, we see that if E_i spontaneous state energy level is such that E_i is less than μ . If E_i is less than μ then n of E_i will be $\sum_i g_i$ by exponential. Now E_i is less than μ , therefore this is positive, therefore this is less, so this will be a negative quantity by $k_B T$ minus one. And therefore, this is less than one, therefore denominator of this expression is negative, that means n of E_i is negative. But n of E_i is the occupation probability, so occupation probability cannot be negative, cannot be less zero. Therefore, our assumptions that μ greater than zero is not valid, that is that is regarding the value of the chemical potential for a Bose gas, which should either be negative or utmost equal to zero.

(Refer Slide Time: 04:01)

Worked Example 105

Problem
Determine $\frac{d\mu}{dT}$

Solution

$$\frac{d\mu}{dT} = \frac{\left\{ \frac{\partial}{\partial T} f(E) \right\}}{\left\{ \frac{\partial}{\partial T} f(E) \right\}}$$
$$= \frac{(E - \mu)}{T} > 0$$

Next, we are asked to determine the temperature dependence of the chemical potential; in other words, the derivative with respect to temperature of μ . In order to do this, we note that we can write this as $\frac{d\mu}{dT}$ of $f(E)$ divided by... Now the $\frac{d\mu}{dT}$ of $f(E)$ is $\frac{\partial}{\partial T} f(E)$ then exponential $e^{-\frac{E - \mu}{k_B T}}$ times $\frac{d}{dT}$ of this, so minus one by $k_B T^2$ of $E - \mu$ that is $\left(\frac{E - \mu}{k_B T^2} \right)$ derivative. Whereas, if you differentiate $f(E)$ with respect to μ then that will be $\frac{\partial}{\partial \mu} f(E)$ again exponential $e^{-\frac{E - \mu}{k_B T}}$ times minus one by $k_B T$. So that will be the values of this derivative, so the ratio of these two which is $\frac{d\mu}{dT}$ is this divided by this, which will give me $e^{-\frac{E - \mu}{k_B T}}$ by T . And since μ is always less than or equal to zero, this will become positive definite and E is always zero or positive – greater than zero. Therefore, this will be greater than zero. So, that is see how we determine the temperature derivative of the chemical potential.

Worked Example 106

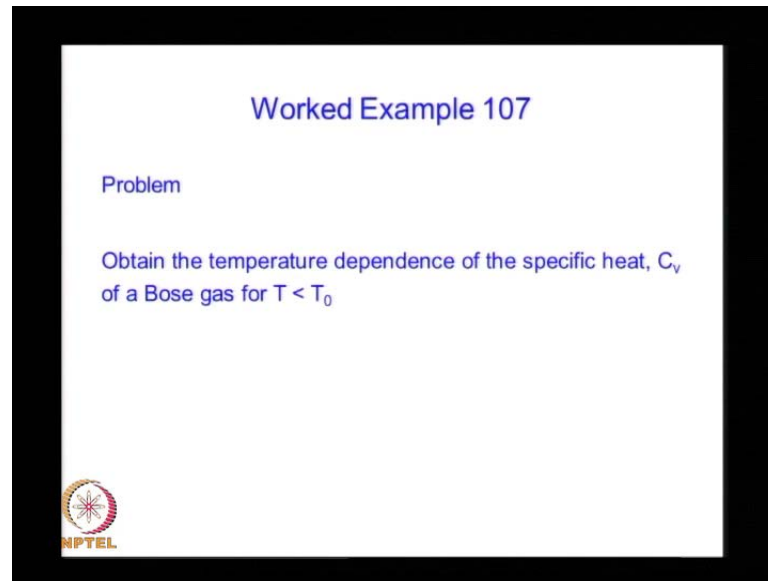

Problem
Discuss the temperature variation of μ for $T < T_0$

Solution
If at $T = 0$ μ has some negative value, as T increases μ increases and becomes zero at some temperature T_0 . Thereafter it stays at this value when the temperature is increased further. T_0 is the Bose Einstein condensation temperature.

In the next example, we are asked to discuss what happens to the temperature variation of μ for $0 < T < T_0$, where T_0 is so called Bose Einstein condensation temperature, which we discussed in the lecture. So, let us say at $T = 0$ K, suppose μ has some negative value then we also know that $d\mu/dT$ is positive; that means, as temperature increases μ increases, that is μ increases with temperature. So, as one changes increases the temperature from absolute zero as T increases μ becomes it also increases; that means, it takes negative values approaching 0. So, eventually μ becomes equal to zero this is what happens at $T = T_0$. This is how we defined T_0 . Once it reaches $T = T_0$, since $d\mu/dT$ is positive so that means, μ has to stay constant at this value for at higher temperatures that is the temperature variation of μ .

Worked Example 107

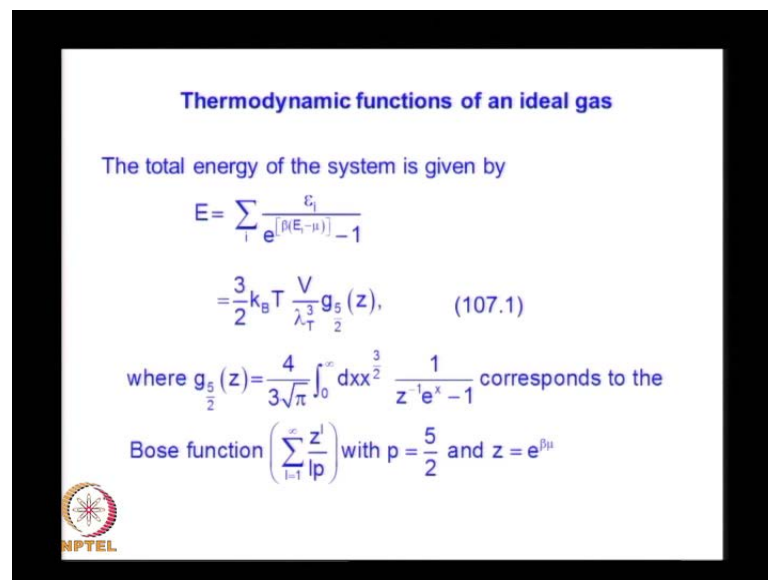

Problem

Obtain the temperature dependence of the specific heat, C_V of a Bose gas for $T < T_0$

Having got the temperature variation of the chemical potential. We are asked to discuss the temperature variation dependence of the specific heat C_V for a Bose gas T less than T_0 and also T greater than T_0 .

(Refer Slide Time: 11:24)

Thermodynamic functions of an ideal gas

The total energy of the system is given by

$$E = \sum_i \frac{\epsilon_i}{e^{\beta(\epsilon_i - \mu)} - 1}$$
$$= \frac{3}{2} k_B T \frac{V}{\lambda_T^3} g_{\frac{5}{2}}(z), \quad (107.1)$$

where $g_{\frac{5}{2}}(z) = \frac{4}{3\sqrt{\pi}} \int_0^\infty dx x^{\frac{3}{2}} \frac{1}{z^{-1}e^x - 1}$ corresponds to the Bose function $\left(\sum_{l=1}^{\infty} \frac{z^l}{l^p} \right)$ with $p = \frac{5}{2}$ and $z = e^{\beta\mu}$

We know that the specific heat is the temperature derivative of the internal energy. Therefore, we first determine the internal energy and then differentiate the expression with respect to temperature to obtain the specific heat. The energy is given by $\frac{3}{2} k_B T \frac{V}{\lambda_T^3} g_{\frac{5}{2}}(z)$ an expression that we discussed in the lecture $g_{\frac{5}{2}}(z)$.

Where $g_{5/2}(z)$ is the following expression $\frac{4}{3\sqrt{\pi}} \int_0^\infty dx x^{3/2} (1 - z e^{-x})^{-1}$. This is the Bose function, which we discussed in terms of the Riemann-Zeeman zeta function in the lecture and has the value $\sum_{l=1}^\infty z^l l^{-5/2}$; $z = e^{-\beta\mu}$ and the summation is over l and z is e to the power $\beta\mu$.

(Refer Slide Time: 13:54)

For $T < T_c$, $Z=1$ and one has $g_{5/2}(1) = 1.342$.

Then, the specific heat $C_v = \frac{\partial E}{\partial T}$ is obtained as

$$\frac{C_v}{k_B N} = \frac{15}{4} \frac{v}{\lambda_T^3} g_{5/2}(1), \quad (107.2)$$

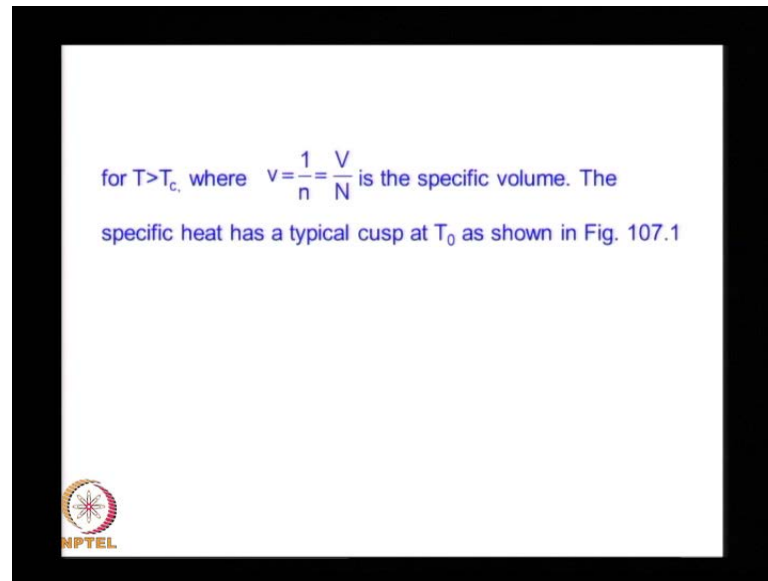

For $T < T_c$, and

$$\frac{C_v}{k_B T} = \frac{15}{4} \frac{v}{\lambda_T^3} g_{5/2}(Z) - \frac{9}{4} \frac{g_{3/2}(Z)}{g_{1/2}(Z)}, \quad (107.3)$$

So, let us first discuss what happens for the temperature range T greater than T_{naught} ; here z equals 1, since μ is zero. Therefore, $g_{5/2}(1)$ has the value 1.342. Therefore, the specific heat, hence we can substitute this here and the specific heat which is de by dt is such that this is $N k_B$ into $15/4 v$ by λ cube into $g_{5/2}(1)$ for k less than T_{naught} . In the same way, we can get c_v equals $N k_B$ into $15/4 v$ by λ cube into $g_{5/2}(z)$ minus $9/4 g_{3/2}(z)$ divided by $g_{1/2}(z)$, this is got by simple differentiation of the expression for the average energy total energy.

(Refer Slide Time: 16:54)

So, this is how we obtain the specific heat and well we can write small v in both cases where v is V by N - the specific volume.

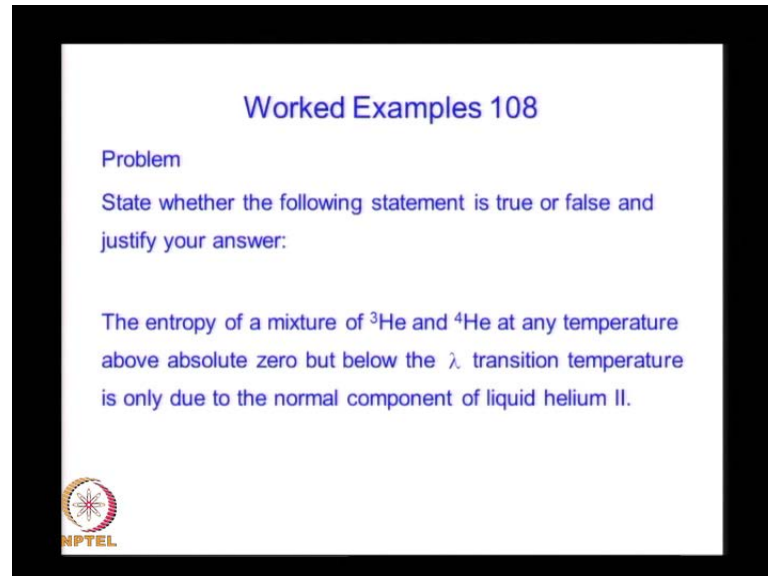

(Refer Slide Time: 17:17)

So, the variation of the specific heat is shown in figure and looks like this. So, let us plot it as C_v by $N k_B$ and T -by- T_0 . So, this has when T equal to T_0 , it has the value one. So, this goes somewhat like this and then comes down. So, this has a cusp at T equal to T_0 , this is a theoretical variation of the specific heat of an ideal Bose gas, whereas the observed specific heat variation at the lambda point of liquid helium

two is more like this is more or less right, but this goes like this. So, that is more like the observed variation of liquid helium two for around T_λ .

(Refer Slide Time: 19:48)

Worked Examples 108

Problem

State whether the following statement is true or false and justify your answer:

The entropy of a mixture of ^3He and ^4He at any temperature above absolute zero but below the λ transition temperature is only due to the normal component of liquid helium II.

Next example is in the form of a true or false question for a given statement. We are asked to state whether the given statement is true or false and justify the answer. What is the statement? The entropy of a helium 3, helium 4 mixture at T greater than zero K, but plus you can write it as for zero less than T less than T_λ . This entropy is only the entropy of the normal component, normal component of liquid helium 4. This is the statement.

(Refer Slide Time: 21:07)

Solution

Answer:
False.

Even though superfluid ^4He carries no entropy and ^3He has no configurational entropy because it obeys Pauli principle, (The configurational entropy of any Fermion is $k_B \ln 1 = 0$) gaseous ^3He , like an electron gas, has a specific heat which is proportional to the temperature T while liquid ^3He , below 100 mk, is a fermi liquid with a specific heat of the form $aT + bT^3$ and a corresponding entropy.

Now, the answer is that the statement is true. Now we have to justify, the justification is we know that in the two fluid model according to liquid helium 4 is a mixture of a super fluid and a normal component we discussed this is ρ_s plus ρ_n . Now the super fluid carries no entropy, we saw this when discussing the thermo mechanical effect. Now coming to helium 3, it is a Fermion, because of the odd number of nucleons three. Therefore, for a Fermion, it obeys Pauli-exclusions principle according to which each state has is either occupied or unoccupied.

So, the occupation probability is one or zero. Therefore for the occupied states, the entropy of helium 3 is given by the Boltzmann formula $k_B \log 1$ which of course, is zero. Therefore, the entropy of the helium component helium 3 is zero, and the entropy of the super fluid fractions of the helium four is also 0. So, the entropy which is of this mixture is only due to this normal component of liquid helium 4 that is the answer.
