Lecture - 14
Properties of Convolution

(Refer Slide Time: 00:22)

We have the continuous time system - L T I system, again L T I is very important linear and time invariant and on the left side we have $x(t)$ being applied, we have $y(t)$ emerging as the output. Can we have a means of computing $y(t)$ from $x(t)$ that is the question and as we said we will follow the same steps as we did last time. The first step is to see how to make use of the impulse representation, the impulse representation has to be made use of to obtain the same result that we got earlier for convolution step. So, the impulse representation expression we already have, let us now examine the implications of linearity and time invariance in the continuous time case, when $\delta(t)$ is applied as the input to a system.

(Refer Slide Time: 01:39)

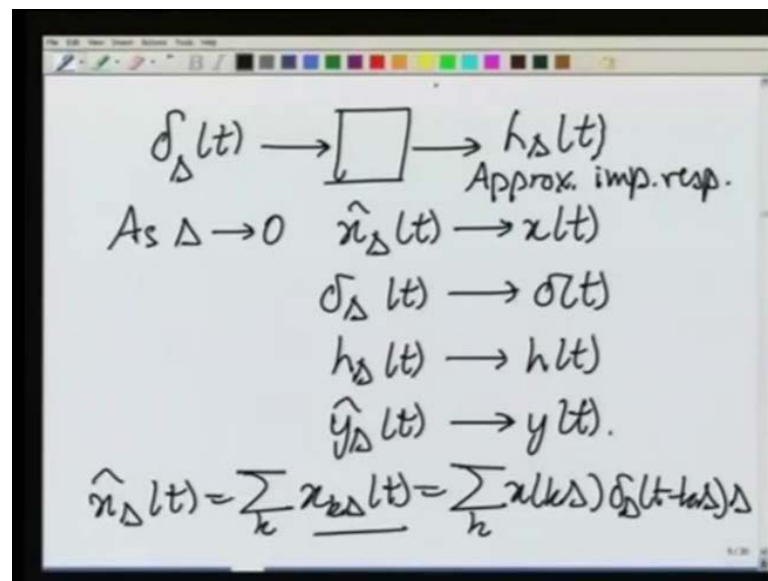

Though delta t is not really a function, we will allow ourselves to apply it as the input to a system. When delta t is applied it has to produce some response from the system, and let us say that the response it produces is $h(t)$. Since, delta t is our impulse $h(t)$ is our impulse response, so if delta t yields $h(t)$ then by time invariance delta t minus t_0 must yield $h(t - t_0)$. This is as I said by time invariance then the next property we want to seek, we will arise out of homogeneity of the system and that is that if we apply a times delta t then we should get an output of a times $h(t)$, this is homogeneity.

Finally, we have linearity, but we will come to linearity in a little while. So, we have these two properties now the linearity will come into that the additivity will come into picture, when we apply the impulse representation. We now have a representation for any $x(t)$, for point we can always represent the value $x(t)$ using the impulse representation. And then combining this $x(t)$'s together to get the entire function $x(t)$, we will see what happens. We now we will apply additivity as well and write out $x(t)$ as the function integral minus infinity to infinity. [FL] point [FL] If we had a [FL] take if we go back to the stair case representation, then we had a stair case representation as follows.

If we go back to the stair-case representation that led to the exact representation, then if you recall we started with $x_\Delta(t)$, $\hat{x}_\Delta(t)$. Let us say that we apply $\hat{x}_\Delta(t)$ to the system instead of $x_\Delta(t)$, instead of $x(t)$. Then when we apply $x_\Delta(t)$ to

the system, it is reasonable to assume that we will not get $y(t)$ as the output, but some modified signal appropriate to $\hat{x}_\Delta(t)$ rather than $x(t)$ and that signal, we shall call $\hat{y}_\Delta(t)$. Now, we will argue that as $\Delta \rightarrow 0$, $\hat{x}_\Delta(t) \rightarrow x(t)$, $\hat{y}_\Delta(t) \rightarrow y(t)$. As $\Delta \rightarrow 0$, $\hat{x}_\Delta(t) \rightarrow x(t)$, $\hat{y}_\Delta(t) \rightarrow y(t)$. This is what we will try to arrange. Now, arguing in the same manner as we did in the discrete time case let us first apply the approximate impulse to our system.

(Refer Slide Time: 06:17)

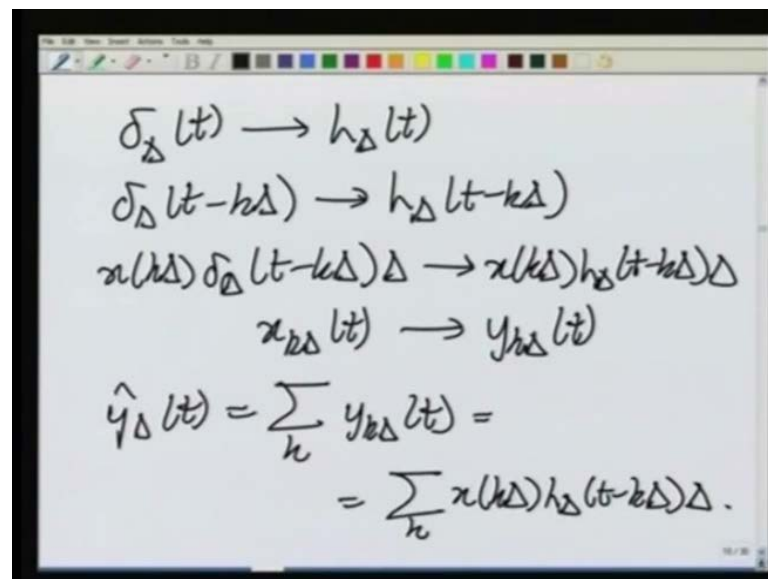

The approximate impulse was $\delta_\Delta(t)$ and when we apply $\delta_\Delta(t)$ to the system we do not expect to get the impulse response at the output. We will only get the approximate impulse response or the modified function the appropriate to $\delta_\Delta(t)$ we will call that $h_\Delta(t)$ this is what we will get at the output. So, now our objective is to make Δ go to 0. So, that $x(t)$ goes to x , $\hat{x}_\Delta(t)$ goes to $x(t)$, $h_\Delta(t)$ goes to $h(t)$ and because of these two changes $\hat{y}_\Delta(t)$ will go to $y(t)$.

So, let us put all that down as Δ tends to 0, $\hat{x}_\Delta(t)$ will become $x(t)$, $\delta_\Delta(t)$ will become $\delta(t)$. Hence, the approximate impulse response that we have over here will become the exact impulse response $h_\Delta(t)$, the approximate impulse response will become $h(t)$. Because of all these changes and improvements $\hat{y}_\Delta(t)$ will become $y(t)$. So, this is what we will work towards we already have an expression that we can construct for the approximate representation, the approximate representation said

that $\hat{x}_\Delta(t)$ was the sum over all k of $x(k\Delta)$, which was equal to the summation over all k of $x(k\Delta) \delta_\Delta(t - k\Delta)$.

Now, let us see what happens as Δ tends to 0. $x(k\Delta)$ that we have over here $x(k\Delta)$ will become a narrower and narrower function of time. Assuming the value $x(k\Delta)$ constant value $x(k\Delta)$ within its support, 0 outside $\delta_\Delta(t - k\Delta)$ will become a shifted dirac delta function occurring at some point. And $x(k\Delta)$ is the point at which x has been sampled at the points $k\Delta$, and these will become more and more numerous and we will populate the entire real axes as k becomes larger and larger for all values of k as Δ gets smaller and smaller. Finally, this multiplication factor Δ that we have to put in this approximate representation that will get smaller and smaller and will eventually, become what we call in calculus as dt . In the mean time using this approximate representation let us see whether, we can get the approximate output $\hat{y}_\Delta(t)$, can we express.

(Refer Slide Time: 10:19)

The image shows a digital whiteboard with handwritten mathematical expressions. The expressions are as follows:

$$\begin{aligned}\delta_\Delta(t) &\rightarrow h_\Delta(t) \\ \delta_\Delta(t - k\Delta) &\rightarrow h_\Delta(t - k\Delta) \\ x(k\Delta) \delta_\Delta(t - k\Delta) \Delta &\rightarrow x(k\Delta) h_\Delta(t - k\Delta) \Delta \\ x_{k\Delta}(t) &\rightarrow y_{k\Delta}(t) \\ \hat{y}_\Delta(t) &= \sum_k y_{k\Delta}(t) = \\ &= \sum_k x(k\Delta) h_\Delta(t - k\Delta) \Delta.\end{aligned}$$

Can we find an expression for $\hat{y}_\Delta(t)$ indeed we can, $\hat{y}_\Delta(t)$ can be obtained using homogeneity time in variance and linearity as the expression. So, let us see if we can obtain an expression for $\hat{y}_\Delta(t)$ using the properties of linearity time invariance, and the approximate impulse response. This indeed can be done because we know that if you applied $\delta_\Delta(t)$ to the system, you would get an output $h_\Delta(t)$. If you therefore, applied $\delta_\Delta(t - k\Delta)$ to the system you would

get $h(t - k\Delta)$ as the output. Finally if you applied $x(k\Delta)$ as the input, and this as we know is just nothing but $x(t)$ of t .

Then we would have to get appropriately $x(k\Delta)$ the scale factor, $h(t - k\Delta)$ times Δ at the output. In short we could invent a new intermediate function, which is you could call the right as say $y(k\Delta)$ as resulting from the left side, which we note to be equal to $x(k\Delta)$ of t . So, you apply $x(k\Delta)$ of t you get $y(k\Delta)$ of t . Now, we have already used here time invariance in the first step, where we have shown that $h(t - k\Delta)$ should give us $h(t - k\Delta)$, we have next used homogeneity to say that if we applied $x(k\Delta)$, $\Delta h(t - k\Delta)$ times Δ . We have used scale scaling twice here because we are scaling by $x(k\Delta)$, as well as by Δ .

Then the corresponding output by the homogeneity property of a linear time invariant system must be $x(k\Delta) h(t - k\Delta) \Delta$. So, the both the scale factors have appeared in the output namely, $x(k\Delta)$ and Δ this together has given us a expression for $x(k\Delta)$ of t , as we have just written in the last line, thus if we say that $\hat{y}(t)$ equals the sum for all k of $y(k\Delta)$ of t . Then we can say that this is equal to the expression, summation overall k $x(k\Delta) h(t - k\Delta) \Delta$.

(Refer Slide Time: 14:13)

The image shows a handwritten derivation on a whiteboard. At the top, it states the limit process: $\Delta \rightarrow 0$, $\hat{x}_\Delta(t) \rightarrow x(t)$, and $\hat{y}_\Delta(t) \rightarrow y(t)$. Below this, a summation $\sum_{k=-\infty}^{\infty}$ is shown with an arrow pointing to an integral $\int_{-\infty}^{\infty}$ over the variable z . The resulting equation is $y(t) = \int_{-\infty}^{\infty} x(z) h(t-z) dz$. A horizontal line follows, and the text below reads: "Convolution expression for $y(t)$ in terms of $x(t)$, $h(t)$."

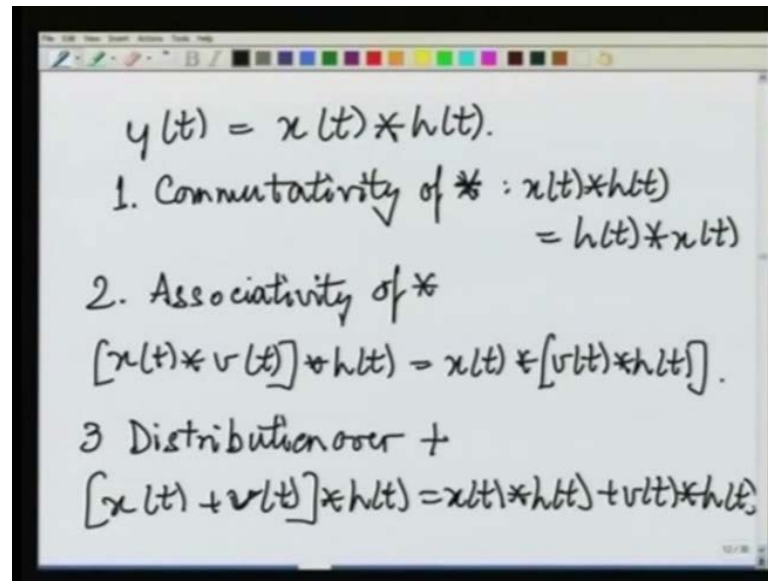

So, $y(t)$ is this expression and here we have used additivity in the last step prior to that we have used homogeneity and further prior to that we have used time invariance. So, because our system that we considered will have linearity time invariance both these properties, we can be sure that all that we have just written is valid, now the final step of taking Δt to 0.

As we take Δt to 0, let us take a various things which happen. The various things which happen will include $x(t)$ becoming $x(t)$ $y(t)$ becoming $y(t)$, as Δt tends to 0. The summation overall k , k equals minus infinity to infinity that we have done will have to be replaced by an integral because the points, $k \Delta t$ will get extremely numerous and will populate the entire time axis. So, we will actually get some continuous variable which we can say is τ , τ going from minus infinity to infinity.

Thus the entire expression for the exact $y(t)$ as Δt tends to 0, will be $y(t)$ equals integral τ equal to minus infinity to τ equal to infinity. That is the equivalent of the summation what has become of the summation $x(k \Delta t)$ is now, $k \Delta t$ is what has become τ . So, $x(k \Delta t)$ will be $x(\tau)$ $h(t - k \Delta t)$ becomes $h(t - \tau)$ and as we already said, Δt will tend to be infinitesimal quantity $d\tau$. This then is the exact expression for the output, when the input is applied and we use the impulse response the exact impulse response $h(t - \tau)$. This is the shifted version the actual thing is $h(t)$ which has been shifted by $t - \tau$. This is the convolution expression for the output of an LTI system in terms of the input and the impulse response, in terms of $x(t)$ and $h(t)$.

So, we have through various very devious and complicated means obtained the same state of affairs, as we had for the discrete time case in the continuous time case as well. We can now construct the output of an LTI continuous time system, if you have a knowledge of its impulse response it's response to the Dirac delta impulse, and if we know the input signal. So, this is the closing of the derivation of impulse response and it is use for continuous time systems, we can now again go through the properties of the continuous time convolution of the convolution formula. We can also take care of the notation if we have $y(t)$ given by the formula just shown.

(Refer Slide Time: 18:08)

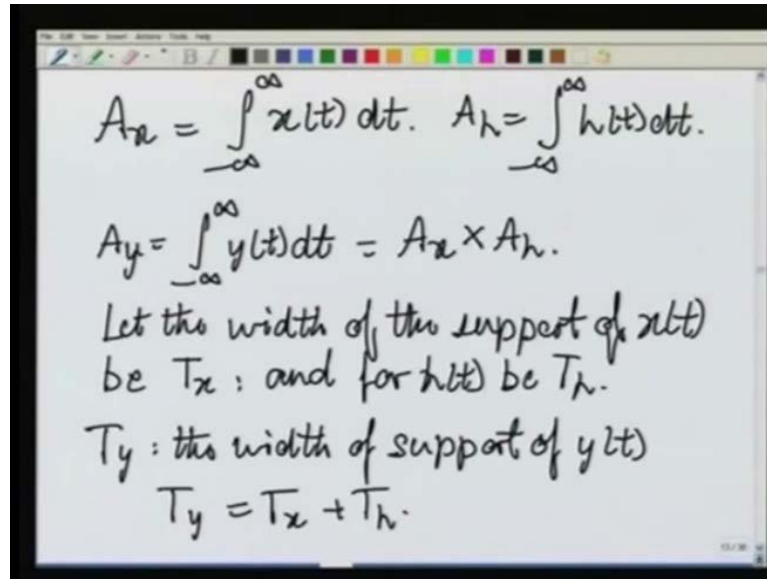

The image shows a digital whiteboard with handwritten mathematical notes. At the top, the convolution equation is written: $y(t) = x(t) * h(t)$. Below this, three properties of convolution are listed and proven:

- 1. Commutativity of $*$:** $x(t) * h(t) = h(t) * x(t)$
- 2. Associativity of $*$:** $[x(t) * v(t)] * h(t) = x(t) * [v(t) * h(t)]$
- 3. Distribution over $+$:** $[x(t) + v(t)] * h(t) = x(t) * h(t) + v(t) * h(t)$

Then we will briefly write $y(t)$ as equal to $x(t)$ convolved this star with $h(t)$. Again, just like with the discrete time convolution as may be expected, we have commutativity of convolution, namely $x(t)$ convolved with $h(t)$ equals $h(t)$ convolved with $x(t)$. We have associativity of convolution that is to say that $x(t)$ convolved with say some $v(t)$, the whole thing convolved with say $h(t)$ is the same as $x(t)$ convolved with the convolution of $v(t)$ and $h(t)$. Finally, we have distribution over addition of signals so, that $x(t)$ plus $v(t)$ convolved with $h(t)$ is nothing but $x(t)$ convolved with $h(t)$ added to $v(t)$ convolved with $h(t)$.

So, these properties are all given and they are very easy to prove the same thing, the same kind of steps we have to be followed that we followed in the previous case. There are many other properties of convolution that the student can try to prove as an exercise. For example, it can be shown that the area under the convolution of two signals is equal to the area to the product of the areas of the component signals. What I mean to say is if we define.

(Refer Slide Time: 20:46)

The image shows a digital whiteboard with handwritten mathematical derivations. At the top, two integrals are written: $A_x = \int_{-\infty}^{\infty} x(t) dt$ and $A_h = \int_{-\infty}^{\infty} h(t) dt$. Below these, the convolution integral is given as $A_y = \int_{-\infty}^{\infty} y(t) dt = A_x \times A_h$. The next line explains the variables: 'Let the width of the support of $x(t)$ be T_x : and for $h(t)$ be T_h .' This is followed by ' T_y : the width of support of $y(t)$ ' and the final equation $T_y = T_x + T_h$.

A_x as the area under $x(t)$ which is of course, given by this integral. Integral over all time of $x(t) dt$ and A_h as similarly, the area under h then it turns out that A_y equal to the area under y is equal to A_x times A_h . So, the convolution of two signals gives us the area product of the component signal areas. So, there is this relationship about areas that you can investigate, and try to prove. Then there are other properties, the support of the convolution.

Suppose, we have two finite support signals let the width of the support of $x(t)$ be say T_x that is to say $x(t)$ is non zero over the interval t_x and 0 elsewhere. The same thing for $h(t)$ be T_h then the width of support of $y(t)$ which we will call T_y of $y(t)$ is given by T_y equals T_x plus T_h , again something that you can prove without too much difficulty. One more result this also pertains to the support, but this is a more strong result is this, let the support of $x(t)$ be actually given in short we are not concerned merely with the width of the support, but with also the location of this support let $x(t)$.

(Refer Slide Time: 23:45)

$$\begin{aligned}
 T_x &= b_x - a_x \\
 x(t) &= 0; \quad t < a_x; \quad t > b_x. \\
 T_h &= b_h - a_h \\
 h(t) &= 0; \quad t < a_h; \quad t > b_h. \\
 \text{if } y(t) &= 0; \quad t < a_y; \quad t > b_y. \\
 \left. \begin{aligned} a_y &= a_x + a_h \\ b_y &= b_x + b_h \end{aligned} \right\} &\rightarrow T_y = T_x + T_h.
 \end{aligned}$$

Let T_x be equal to b_x minus a_x that is to say b_x is the right side limit of the support of $x(t)$ and a_x is the support is the left side limit of the support of $x(t)$. In short $x(t)$ equals 0 for t less than a_x and t greater than b_x . Similarly, let us say that T_h equals b_h minus a_h which is to say that $h(t)$ is 0 for t less than a_h t greater than b_h . Now, what about the limits of the support of y , we want a_y and b_y . If $y(t)$ equals 0 for t less than a_y t greater than b_y , then can we find a_y in terms of a_x and a_h b_y in terms of b_x and b_h .

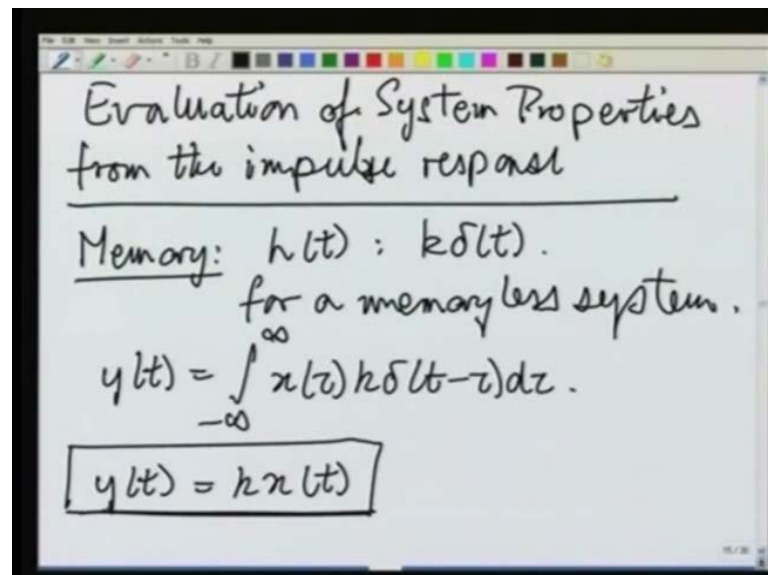

Yes, it can be done, it is simply that a_y equals a_x plus a_h b_y equals b_x plus b_h . In fact you will immediately see that this is what leads us to conclude that T_y equals T_x plus T_h . So, without even doing the convolution you can say a few things about the output of a system. You can say for example, what is the starting point the point where the signal becomes non zero for the first time in the output, on the basis of your knowledge of $h(t)$ and $x(t)$. You can say what is the final non zero point of the output from a knowledge of similar points on $x(t)$ and $h(t)$, you can say what is the area under $y(t)$ knowing the areas under $h(t)$ and the areas under $x(t)$.

So, these are the interesting results about convolution. Now, there are other things that we can go on doing first of all remember that we had several properties of the LTI of systems. We had a property of not having memory that is the memory less property of a system, we had the causality property, we had the stability property, we had

all these properties. Now, if it is really true that an L T I system is fully described by its impulse response, if all the information about the L T I system is covered or bourn by the impulse response.

Then it must also be true that we can determine whether, a system is causal or not whether a system is memory less or not whether a system is stable, or not by just looking at the impulse response by evaluating that fact from the impulse response. Thus we would like to know, how we can find out whether a system is stable or causal or memory less by looking at its impulse response?

(Refer Slide Time: 27:59)

Evaluation of System Properties from the impulse response

Memory: $h(t) : k\delta(t)$.
for a memory less system.

$$y(t) = \int_{-\infty}^{\infty} x(\tau) h(t-\tau) d\tau.$$

$y(t) = kx(t)$

So, system properties evaluation of system properties from the impulse response, first memory, if a system is memory less then we know that the current value of the output only depends up on the current value of the input, right? Therefore, $y(t)$ should not be dependant up on any value of $x(t)$ apart from the point at which $y(t)$ is being calculated, in short $y(t)$ should depend only on $x(t)$. Now, in such a case what can we say about the impulse response or what do we find as a property in the impulse response?

We will find that the impulse response $h(t)$ has to be of the form k times $\delta(t)$ for a memory less system, this is very easy to demonstrate we will use the convolution expression. And just write it out as $y(t) = \int_{-\infty}^{\infty} x(\tau) k\delta(t-\tau) d\tau$. So, this is exactly the shifting property of the

system, this is an expression of the shifting property which we can use for the Dirac impulse that has been applied here, and say that $y(t)$ equals k times $x(t)$.

The only type of linear time invariant system that is memory less is a system where $y(t)$ and $x(t)$ are related in this manner. If $y(t)$ depended up on any other value of $x(t)$ then it must appear in the right side. For example, if we said that $y(t)$ was equal to two times $x(t)$ minus t naught or if it was an integral of the values of $x(t)$ over some interval of time. In all these cases, $y(t)$ would not have this value would not have this form now, it has this clear form which says that $y(t)$ depends on $x(t)$, this is the only form possible for an L T I memory less system. You can see that it is linear and time invariant if $y(t)$ equals k times $x(t)$.

So, it is a it is linear time invariant it is also memory less as we can see and for such situations, we have $h(t)$ given by $x(t)k\delta(t)$ $x(t)h(t)$ equals $k\delta(t)$. So, this you can immediately see if $h(t)$ equals $k\delta(t)$ then it is a memory less L T I system. Now, what about causality if an L T I system is causal then what how does that manifest itself in the impulse response. This is an interesting question and it has a very, very straight forward answer in terms of some of the results that we have stated, though not proved. Remember that the support of the output can be obtained in terms of the support of the input, and the support of the impulse response. Now, suppose a system is causal and to this system we apply any $x(t)$ which is 0 up to t naught and non zero only subsequently so let.

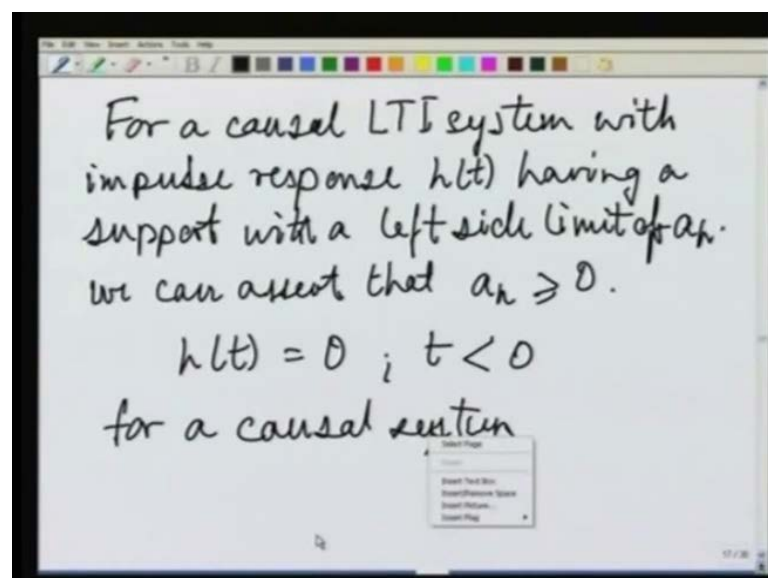

(Refer Slide Time: 33:36)

Causality:
 Let $x(t) = 0 ; t < t_0$
 If the system is causal,
 $y(t) = 0 ; t < t_0$
 $a_y = a_x + a_h$
 $b_y = b_x + b_h$
 Here $a_x = t_0$
 $a_y \geq t_0$
 $a_h \geq 0$

$x(t)$ be equal to 0 for t less than t_{naught} , and it is probably non zero for all t greater than t_{naught} or at least for some of the t is greater than t_{naught} , but it is definitely 0 for t less than t_{naught} . Suppose, you have this then if the system is causal, what is one certain thing that we can say about the system one definite fact that we can state about the output. Irrespective of even whether the system is linear or time invariant we can say that if $x(t)$ is equal to 0 up to t equal to t_{naught} then $y(t)$ must also be 0, for all times t less than t_{naught} . In short for a causal system if the system is causal $y(t)$ also equals 0 for t less than t_{naught} , it could even be 0 for some interval of time after t_{naught} , but that does not concern us we have to be sure that this much is certainly applied.

So, from this what can we say about the support of $h(t)$ earlier we had a result that if a_x and b_x are the limits of support of $x(t)$ a h , and b_h the limits of support of $h(t)$ a y b y the limits of support of $y(t)$. Then we had that a_y I mean that a_y equals a_x plus a_h , b_y equals b_x plus b_h . Now, our concern now is with the left side limit of the support that is t_{naught} , in this case a_x equals t_{naught} , t_{naught} and we require since, the system is causal that a_y must be greater than or equal to t_{naught} . Therefore, if a_y is greater than equal to t_{naught} and a_x is t_{naught} then using this along with this result that a_y is a_x plus a_h . We can immediately see that a_h must be greater than equal to 0.

(Refer Slide Time: 37:17)

So, since the system is linear and time invariant, we assume that it have an impulse response, and if there is an impulse response, then the impulse response function, which

gets convolved with $x(t)$ to get $y(t)$, must have this property that its left side support limit, that the limit of the left side limit of its support must be greater than equal to 0, it cannot be less than 0. So, we will put this down for a causal system.

L T I system with impulse response $h(t)$ having a support with a left side limit of a h , we can assert that $h(t)$ is greater than equal to 0. Another way of just saying this is to say that $h(t)$ is equal to 0 for t less than 0 not less than equal to 0, for t less than 0 for a causal system. So, that takes care of a causal system. So, we can by inspection say whether a system is causal or not by looking at its impulse response.

So, as we expected it is indeed the case that both causality, as well as memory. The presence or absence of memory can be discovered by just examining the impulse response, this as we said must be the case if the impulse response says, all that there is to be said about an L T I system. We should be able to reduce all the properties of the L T I systems from the impulse response and that takes us to the third property of stability.

(Refer Slide Time: 39:59)

Stability: Bounded $x(t)$ \rightarrow Bounded $y(t)$.

Convolution Integral

$$y(t) = \int_{-\infty}^{\infty} x(\tau) h(t-\tau) d\tau.$$

$$|y(t)| = \left| \int_{-\infty}^{\infty} x(\tau) h(t-\tau) d\tau \right|$$

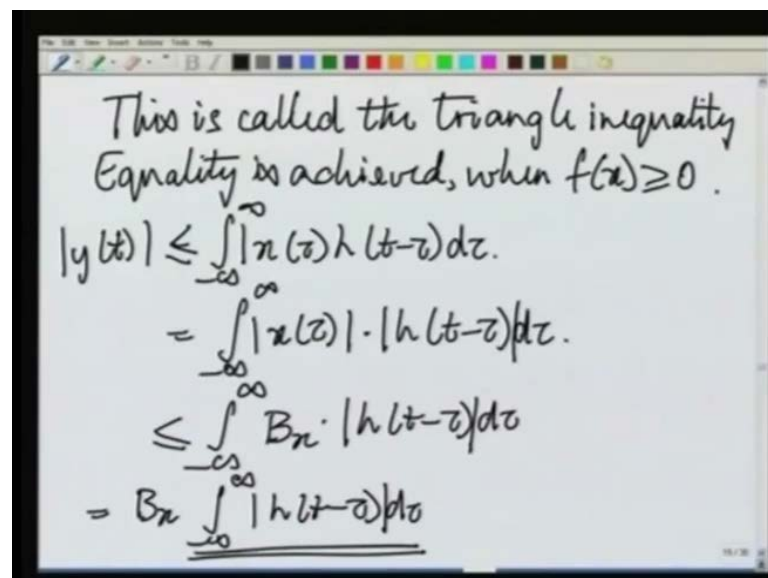

$$\left| \int_{-\infty}^{\infty} f(x) dx \right| \leq \int_{-\infty}^{\infty} |f(x)| dx.$$

Remember that our definition of stability was that bounded inputs should yield bounded outputs, bounded $x(t)$ must imply a bounded $y(t)$. So, let us see where this takes us, we again go back to our expression for the impulse response for the output, in terms of the impulse response that is the convolution integral. $y(t)$ equals the integral from for all time of $x(t)$ rather $x(\tau)$ a different variable $h(t-\tau) d\tau$ this is what we have. Now, let us note that $y(t)$ is a summation of functions like this is an integral of values of $x(t)$. so, we

are now interested in a bound existing for $y(t)$, when a bound exists for $x(t)$. So, a bound as we know is a limit on the absolute value of the function. So, what is the absolute value of $y(t)$? The absolute value of $y(t)$ is this, we have to evaluate the absolute value of the integral.

Now, one very well known property about any integration is this, if you have an integral of some function and you take its absolute value that number is always less than, or at just equal to the integral of the absolute value of the integrand itself. In short we can say that for any situation integral of the absolute value of the integral of say $f(x) dx$ is less than, or equal to integral of the absolute value of f . This property is called the triangle inequality, this is true and we can say these two things about the triangle inequality that well let me put that down.

(Refer Slide Time: 43:39)

The image shows a handwritten derivation of the triangle inequality for integrals on a whiteboard. The text is written in black ink. At the top, it says "This is called the triangle inequality" and "Equality is achieved, when $f(x) \geq 0$ ". Below this, the derivation starts with the absolute value of $y(t)$ less than or equal to the integral from $-\infty$ to ∞ of $|x(\tau)h(t-\tau)|d\tau$. This is then rewritten as the integral from $-\infty$ to ∞ of $|x(\tau)| \cdot |h(t-\tau)|d\tau$. Next, it shows this is less than or equal to the integral from $-\infty$ to ∞ of $B_x \cdot |h(t-\tau)|d\tau$. Finally, it simplifies to B_x times the integral from $-\infty$ to ∞ of $|h(t-\tau)|d\tau$, which is underlined.

$$\begin{aligned}
 &\text{This is called the triangle inequality} \\
 &\text{Equality is achieved, when } f(x) \geq 0. \\
 &|y(t)| \leq \int_{-\infty}^{\infty} |x(\tau)h(t-\tau)|d\tau \\
 &= \int_{-\infty}^{\infty} |x(\tau)| \cdot |h(t-\tau)|d\tau \\
 &\leq \int_{-\infty}^{\infty} B_x \cdot |h(t-\tau)|d\tau \\
 &= B_x \int_{-\infty}^{\infty} |h(t-\tau)|d\tau
 \end{aligned}$$

Equality is achieved, when $f(x)$ is greater than or equal to 0. That is whenever $f(x)$ is a non negative valued function then equality is achieved. Now, our integrand here is $x(\tau)h(t-\tau)$ which could be negative in some places. So, using that fact over here, we will write this down as $|y(t)| \leq \int_{-\infty}^{\infty} |x(\tau)h(t-\tau)|d\tau$, which is equal to integral over all time of the absolute values of the components the factors of the integrand. So, we have brought it to this state.

Now, let us see how we can maximize the value of this integral, our intention is in some sense malicious. We want to do our best to see if $y(t)$ is unbounded, or rather if the absolute value of $y(t)$ is unbounded. In order to ensure that we will try to consider the

worst case on the right side, the worst case on the right side will result for a signal $x(t)$ which achieves its bound at all times. In short this integral that we have just written here is itself less than equal to the worst case situation where we have instead of absolute value of $x(t)$ the actual bound $x(t)$.

The difference is that absolute value of $x(t)$ is less than equal to b_x at all times t , but here we have replacing it by a constant, which is again equal to the maximum value that $x(t)$ takes or to the bound on $x(t)$. So, we have this $\int_{-\infty}^{\infty} |h(\tau)| d\tau$ absolute value, this is what we have. Now, this is equal to b_x times the integral of $|h(\tau)| d\tau$. b_x could be taken out because we have replaced the function of τ that was $x(\tau)$ by the constant b_x , b_x is constant with respect to τ . So, it is been taken out.

Now, let us understand what is the significance of this integral, this integral is nothing but a time shifted version of $h(t)$. If you have $h(t)$ and it has an area under it let me call a A then $h(t - \tau)$ will also have the same area by the same logic, if the absolute value of $h(t)$ has a certain area which we will call whatever we like. Then the same absolute value of the shifted version of $h(t)$ that is $h(t)$ shifted to $h(t - \tau)$ will also have the same area. In short what we are looking at is the absolute area of $h(t)$, B_x times the absolute of $h(t)$ this means.

(Refer Slide Time: 48:36)

$$|y(t)| \leq B_x \cdot \text{Abs. area of } h(t)$$

$$\int_{-\infty}^{\infty} |h(\tau)| d\tau < \infty$$

$$|y(t)| < \infty$$

$$B_y = B_x \int_{-\infty}^{\infty} |h(\tau)| d\tau$$

If $h(t)$ is absolutely integrable, then the system will be stable.

That we have $|y(t)|$ summarizing as less than equal to B_x times the absolute area of $h(t)$. Where the absolute area of $h(t)$ is nothing but integral overall time of $|h(\tau)| d\tau$, if this

quantity that we have called the absolute area of $h(t)$ is finite. If this is finite, then $B \times$ times this is also finite, because any finite number multiplied by another finite number is always a finite number and thus $\|y(t)\|$ will also be finite. Therefore, we will have a bound for $y(t)$. In fact we can find that $\|y(t)\|$ is bounded by a bound for y can be found in the form $B \times$ times the absolute integral of $h(t)$. Summarizing we can say that if $h(t)$ is absolutely integrable, then the system will be stable.
